The general term of metabolism is applied to this ceaseless, while life exists, round of chemical exchanges; the terms anabolism, to represent constructive metabolism, and katabolism to represent destructive metabolism.

Anabolism is the constructive, katabolism, the retrograde metamorphosis of tissue. These terms include evidently both morphological and chemical processes. The interrelation of the two is inseparable. It would be impossible to say that either was fundamental. Without the cell substance there would be no chemical exchanges, and without the chemical exchanges no cell substances could be maintained. The mystery of why these chemical exchanges take place need not detain us. This mystery ever confronts us in each blade of grass, in every unicellular, as well as in the higher and more complex, organisms. Nor do I think it essential to inquire to what extent these exchanges are under the control of the nervous system. Neural impulses may admittedly initiate nutritional processes. Gaskel would go so far as to say that constructive metamorphosis (anabolism) is presided over by one set of nerves, while destructive metamorphosis (katabolism) is presided over by another. But it may be borne in mind that just as that form of energy known as heat is essential to start the oxidation of coal or wood, so that its potential energy may be liberated into kinetic or actual energy, so in the same manner may the nervous impulses initiate that explosion, of muscle-substance, for example, whose ultimate result is exhibited in the form of muscular contraction, heat, and *electricity*. The chemical tissue changes have stored energy, the gunpowder, so to speak, while the nerves represent the match, which, in setting free the potential, sets up the actual energy or explosion. Were the point that nerves control nutrition pressed too closely, we might ask what controls the chemical exchanges of the nervous centres, whence emanate these primary controlling impulses. From this point of view, it would seem that the vegetative capacity of the cell, viz.: its chemical capacity, was the ultimate limit of present knowledge. It is, however, enough to satisfy the requirements of the theory I wish to suggest, to rest at this point, viz.: that living is a process of chemical exchanges, and take a new departure.

Transformation of the Energy of Chemical Affinity into Electrical Energy in Living Tissue.—To have established that living tissues are both built up and broken down by the metabolic process of chemical exchange establishes equally what we know to be the fact, that energy is both stored up and set free in these tissues. The radiant energy of light and heat is stored, in potential form, by the plant, and in the shape of food becomes living animal tissue. This tissue in the process of life is attacked by oxygen, suffers oxidation or combustion, and consequent disintegration, becoming converted into simpler elements, constantly given off by the skin, kidneys, and lungs (carbonic acid, urea, creatinine, water, etc.), and releasing potential energy into the actual or kinetic energy of heat, mechanical force, and electric energy. To avoid confusion, we will, for the present, limit our attention to combustion changes, since these predominate in the living animal tissue, and since this fact affords us the ground-plan of our structure.

"The potential energy of chemical affinity in living tissue," says Halliburton, "is transformed, and exhibits itself partly as heat, partly as electrical change, partly in the form of mechanical work." In the animal organism the phenomena of electro-motive force and heat may be conceived of as primarily due to oxidation and to be related to each other in sliding scales, one predominating at the expense of another, in certain cells and groups of cells, in both normal and abnormal processes. This view will be developed under electro-physiology. Of these phenomena, the electro-motive are grouped under the title of Animal Electricity.

Animal Electricity.—There is every reason why the human body, a living mass of diverse constituents in chemical action, should exhibit currents, and as a consequence possess electro-motive sources or centres whence spring these currents. Indeed, it seems most probable that for every current discoverable there must be an infinite number which are no sooner originated than they are extinguished by immediate short circuit, or which are employed in further acts of metabolism. A parallel to the condition of short circuit exists in a fact well known to the management of galvanic batteries. Chemically pure zinc is unattacked by acidulated water. The ordinary zinc is impure by reason of lead, arsenic, and cadmium. The impurities form with the zinc little local galvanic couples, in which the zinc is the metal attacked; that is, the zinc is electro-positive to any of the other three. These form closed circuits, and currents ensue, with destruction of the zinc, and to prevent this, battery zincs are amalgamated with mercury. The elementary facts of contact electricity alone would teach us that living tissue should generate currents. Any two metals which touch each other exhibit opposite electric charges. Between zinc and platinum the difference of electric change is very marked. Volta arranged a series of metals in which every successive one was positive to the one next lower in the series. Two dissimilar liquids in contact likewise show a difference of charge, as well also as a liquid and a metal, or even a hot and a cold metal; in short, all heterogeneous masses brought into contact exhibit this electrical difference. And if a difference of charge exists at contact, we know that in order to maintain a continuous flow between the two substances in contact, it is only necessary that chemical action be maintained between one of these and an electrolyte, while the electrolyte bathes both; under these circumstances the chemical action is initiated by the greater affinity of the oxygen atom for zinc than for copper, for instance, and by the potentially free state of the atoms in the electrolyte, as must be the case in all electrolytic conduction. These are conditions which exist in the living animal: we have the diverse substances in contact; the oxygenated blood and lymph electrolyte, and the chemical actions, as, for instance, the avidity for oxygen, which are the very essence of metabolic exchanges, particularly the katabolic.

Electricity, whatever it may be, is everywhere, but we know it as such only when its equilibrium is disturbed and we have too much in one place and too little in another, and term the extremes positive and negative. As Dr. Oliver Lodge has said, if the air were always in a state of perfect calm we should not know that such a thing existed. We are only conscious of it when its equilibrium is disturbed and we feel and see the effects of the winds. So in animal currents, they exist, though not observable, except in special instances and when sought for. The living organism is exactly constituted to effect this disturbance of electrical equilibrium. In short, I see no reason why we should not assume that there is no chemical exchange in a living organism so minute as not to produce, under proper conditions of circuit, its due quota of electric polarity and consequent current. Some of these currents, under favorable conditions of conductive arrangement of tissues, are demonstrable as animal currents.

The existence of electric currents in living tissue was first brought into prominence by the discovery of Galvani, who believed that the current he had discovered had its origin in the tissue brought into contact with his two dissimilar metals. Fabronius and Volta traced the origin of the current to the metals employed, and the former again to the chemical action existing or set up and continued in one of them. The subject of animal currents was extensively studied by Nobile and Matteucci. But it is to the indefatigable labor of DuBois-Reymond that we owe the greater part of what is known about the phenomena of electric currents in animal tissues. He also brought the phenomena which he studied into relation with the normal irritability of nerve and muscle, and established most important electro-physiological laws. To him we owe the terms "current of the nerve or muscle in repose," and "negative oscillation," expressive of the facts observed, and "electrotonus."

To explain the generation of a current in a muscle DuBois-Reymond conceived of the division of a muscle into cylindrical "elements," which he termed electromotor elements, each one the seat of an electro-motive force, which rendered the element positive at its longitudinal surface and negative at its end. The element is substantially a fragment of the muscle. These elements assembled constitute the entire muscle, which, in turn, and as a whole, exhibits a similar relation of polarity. The element, in its turn, was made up of molecules, and to a rotatory movement of the molecules in the interior of the element, by reason of which the position of their poles and equators changed position, he attributed the changes in potential difference observed in the currents of repose, and in negative oscillation. The word molecule, in the sense in which DuBois-Reymond uses it, does not correspond to the ordinary use of the word, but to an aggregation of the usual chemical and physical molecules. Essentially the same construction plan he applied to nerves. To explain electrotonus, he claimed that the nerve molecules change their position under the influence of the constant current, and that this change produces a different distribution of the "tensions" at the surface of the nerve. Upon arresting the passage of the current the change of position ceases. The change in the position of the molecule changes the state of the nerve as regards its irritability, and explains the facts of "electrotonus."

Schiff carefully re-examined the subject, and regards the negative oscillation as a distinct current due to functional activity. This current he termed the "current of action." This current of action is admitted by Hermann and Engelmann.

DuBois-Reymond's views, both as to the mechanism for the production of currents, and as to his electro-physiology, enormously as they have contributed to the advance of the subject, are vigorously denied by many authorities.

For my own part, it would seem that the rotatory molecules with their polar and equatorial differences of potential, imagined by DuBois-Reymond, would furnish an electric current upon a synchronous and symmetrical movement. But this current would not correspond to the constant current ordinarily observed in animals, but would resemble the shock imparted by electric fish. In the torpedo and gymnotus a series of disks is formed into columns, bathed in an albuminous fluid. The mass is muscular and contractile; when the columns lengthen or contract, their surface, in relation to the fluid, varies, and the potential difference of each in relation to the fluid is varied; the sum total of the varying potentials of several thousand disks and the fluid contiguous to each, is sufficient to produce the familiar shock, comparable to that received from a Leyden jar. The comparison to DuBois-Reymond's moving molecules seems to me to be a fair one.

Matteucci is the originator of the idea that chemical action in living tissues generates electric currents. Becquerel attributed these currents to osmosis, and has demonstrated that a constant current is established by almost any two fluids, differing in density or otherwise, and separated by a conducting membrane. The same view has been ably advanced by Trowbridge, of Harvard University. The well known Porret and Quincke phenomena are examples of the osmotic action referred to. The vast network of capillaries in the animal body furnish an admirable arrangement for osmotic generation of the current.

D'Arsonval attributes the current, that is to say, the difference of potential which give rise to it, to a change of form in the muscle—"the muscle, in contracting, diminishes its surface, which, as a consequence, becomes negative; on the contrary, in relaxing, it augments its surface, and this then exhibits a positive potential." [1]

Lippmann has shown that the changes of surface between two substances which have an action one upon the other are sufficient to determine a difference of potential, and consequent momentary current. Larat [1] has briefly but admirably summed up the chemical and physical views upon which are based a theory now gaining adherence. This theory, he remarks, "rests upon the chemical actions (Matteucci) or the physical (Becquerel) which take place in the tissues, under the influence of cellular life, actions which are completed by the faculty which organic tissues possess, in particular the nerves and muscles, of transforming directly electricity into physiological function.

"The organism, in this case, would be analogous to a thermo-electric pile, for example, with the difference, that the thermo-electric pile would receive heat and give out electricity, while the muscle receiving electricity would give out movement; the nerve, according to its function, motor impulses, or of sensation and trophic action.

"This last point, the transformation of energy by the living organism, has only lately come into science, it has not yet received sanction from actual proofs, and has not even been announced as clearly as I here announce it. But it is so in accord with all the other physical phenomena, it explains so well the therapeutical action, that it merits, at least, an attentive examination."

Confining attention for the present to the simple theoretical contention that the chemical exchanges, principally oxidation, incident to the life activity of the cells of the living organism, viz.: their metabolism, are the initial cause of animal electric currents, the question at once arises, granting that the potential difference is thus set up, how are the material parts so related as to constitute a voltaic couple? Obviously, in no such manner as described by DuBois-Reymond, but rather in the animal cell, which is the seat of the chemical exchanges, or in the relation of the cell to its electrolyte, the blood and lymph. To avoid any definite expression as to what actual parts of the cell and its environments constitute the voltaic cell, I have used the general term, protoplasmic foci, assuming, what must be granted, that if the currents exist, and if they are due to chemical exchanges, that corresponding protoplasmic foci must also exist.

As regards animal currents in general, it is found that, *a*, contracted muscle is negative to living muscle at rest; *b*, that cut surfaces are negative to sound surfaces; *c*, that excited parts are negative to inactive parts. These three fundamental facts of animal electricity are consonant with the point I wish to make in treatment. I will here merely point out that in physiological experiments, which demonstrate animal currents and polarity, the external circuit is the one commonly referred to, and that if a contracted muscle, a cut surface and an excited part is negative when tested in its external circuit, it is positive in its internal circuit, where the active chemical changes are going on. It is with the polarity of the internal circuit that we are are now dealing, though for simplicity it is often convenient to refer to the direction of a current rather than to the initial polarity. We may at this point advance the preliminary generalization that since the chemical energy of the tissues can undergo a transformation into heat, mechanical, electric, or other energy, this second form of energy can in turn be used to set up chemical affinity in the same tissues. Witness in physics the principles of the storage battery. The bearings of such a generalization as regards heat and mechanical force need not here be touched upon. Both affect the chemical exchanges of metabolism, and compared to electricity, the idea of polarity may be expressed in terms of heat and cold, and compared to mechanical force, in terms of its absence (rest) or its presence (applied mechanical force). Our principal interest now centres in pursuing the subject as regards electricity.

And, having built upon the view that the chemical

[1] Traité d'Électricité Médicale, par le Dr. G. Bardet. Paris, 1884.

[1] Précis d'Electro-Thérapie par le Docteur Larat, page 106. Paris, 1890.

activity of the living animal cell and its surrounding fluids may be responsible for the existence of animal currents, I propose two deductions: 1, A law of electro-therapeutics here developed; 2, a law of electro-physiology, to be developed in a second section of this article.

The law of electro-therapeutics is that *metabolism exhibits an electric polarity which may be opposed or coincided with by an applied extraneous electric polarity with the effect of respectively arresting or augmenting the chemical processes which produce the metabolic polarity.*

That we may expect to obtain alterations in nutrition, often referred to as trophic changes, by aid of the electric current will readily be granted. These effects have been carefully studied by Onimus and Legros, by Erb, Remak, Benedikt, and others. Such alterations, in the absence of any definite understanding of their nature, have been classed under the ambiguous term of catalytic effects, and are variously ascribed to electrolysis, vaso-motor changes, cataphoresis, and further unknown reactions in the intra-polar region. Were these obscure and inexplicable trophic effects the goal I desire to reach, I should not have attempted this contribution to the subject. The query I put is, Is there not some clue furnished by the actual processes of health and disease in living tissue which shall serve as a guide to treatment by electricity? The problem I would solve is to find some reliable basis on which to found our treatment—some explicable way out of the uncertainties among which we grope. It is this problem which I suggest may be solved by appealing to an electro-chemical basis of normal and morbid processes in living organisms, and upon this basis founding a special and invariable law which may serve as a definite guide to electro-therapeutics. To attain to this proposed solution it is essential to inquire further into: 1, The nature of the metabolic or chemical exchanges, their possible polarity, and the relation of these polarities to health and to disease; 2, the nature of the chemical effect of the current as to the characteristics of its poles; and to ask, 3, if the latter cannot be intelligently arrayed against the former to constitute a system of rational electro-therapeutics?

As thus presented, the crucial question becomes, in morbid processes, which pole shall be applied to a given focus of disease? Upon the answer to this question depends, I believe, the success or the failure of our treatment. To the lack of any fixed procedure in this respect, I attribute the great diversity in results obtained—results at one time brilliant and convincing, at another disappointing.

The Polarity of Metabolism.—Reverting to the fact that one transformation of the chemical energy of the process of living is into electric energy, we must admit that both physiological and pathological processes are, when such a transformation occurs, electro-motive sources or focuses. Such focuses are demonstrable in the well-known facts of animal electricity, and they are a probable accompaniment of all metabolic exchanges. And these electro-motive sources must be electro-positive, since every electro-motive source is, as I claim, and attempt to explain later on, initially electro-positive to some other electro-negative element (tissue) or portion of tissue, bathed in the same electrolyte. A striking comparison may be made to the zinc of the ordinary zinc-copper cell. In its internal circuit, the electric polarity and consequent current starts from the contact of the zinc with the electrolyte, and one result is the oxidation of the zinc; the initial cause of the appearance of electric energy is, as was stated when referring to contact electricity, the greater affinity of the oxygen for zinc than for copper, and, as long as the zinc and the oxygen last and an external circuit is provided, the electric energy will continue to be released by the exhibition of the chemical affinity between the two.

In the same manner, in the living animal body, heat and electric energy are the direct results of oxidation or combustion (katabolism), and the starting-point of this activity is an electro-positive starting-point. We have here the clue we are searching for; it brings us to the fundamental point I would suggest, and this is, that all active centres of living, of chemical affinity in living tissue, of metabolism, constructive and destructive, of physiological and pathological processes in living tissue; in short, all such centres of health and of disease are initially electro-positive to some other electro-negative portion of the same tissue or surrounding or neighboring tissue and media.

It is merely incidental to the above statement to restate as a basis of medical treatment by electricity that all active centres of disease are initially electro-positive. If this statement can be maintained to be true, it furnishes the physician with an exact basis of treatment—an element hitherto lacking in electro-therapeutics. Physiological experiment would seem to corroborate this view. Thus, as we have seen, excited are negative to inactive parts, the contracting muscle is negative to the muscle at rest; in other words, exhibits negative polarity (as does the zinc), which is equivalent to the statement that such parts are positive within the electrolyte, *i.e.*, in the internal circuit.

By means of the capillary electrometer, Waller [1] demonstrated an electrical variation in the human heart corresponding with the systole of the ventricles, and similar to the negative variation or action current, already often demonstrated in the lower mammalia. He assumed that negativity (positivity in the internal circuit) is the sign of functional activity. Bayliss and Sterling,[2] carefully repeated Waller's experiments. Taking the "wave of negativity" as an index of the wave of contraction, they found that the contraction was a single wave, passing from one end of the heart to another, the negativity at the base preceding that at the apex.

Health and Disease in their Relations to Metabolic Polarity.—The health of the individual or the tissue may be defined to be the stable equilibrium of tissue exchange, established between its intake and its output, between, on the one hand, the food and oxygen consumed, and, on the other, the excretions. This amounts to saying, that disease is a perversion of metabolism, meaning by metabolism, "the sum total of the chemical exchanges that occur in living tissue"[3] In health, the balance is maintained; in disease, it would range above or below this standard of stability; the chemical exchanges would be excessive or deficient, over-active or under-active, but in all events katabolic, destructive, oxidizing, and therefore electro-positive. What is true of the entire organism should be true of a part. It is at this point that the modifying (curative or non-curative) interference of the physician's extraneous electrical current can be exactly applied, and in the following manner expressed for the sake of simplicity in tabulated form:

All active centres of chemical exchanges (metabolism, health, disease) are electro-positive.	Metabolism, chemical exchanges over-active.	An applied + pole increases the activity, *i.e.*, augments the disease.
		An applied − pole decreases the activity, *i.e.*, cures the disease.
	Metabolism, chemical exchanges under-active.	An applied + pole increases the activity, *i.e.*, cures the disease.
		An applied − pole decreases the activity, *i.e.*, augments the disease.

In over-activity the negative pole, in under-activity the positive pole palliates or cures. The plan outlined is exactly parallel to what may be experimentally demonstrated with a primary battery, for instance, a zinc-carbon pair. The chemical exchange takes place at the zinc. This is electro-positive to the carbon; it is the zinc which is oxidized, or which, in other words, undergoes destructive metamorphosis, similar to what takes

[1] Annual Medical Sciences, 1891, vol. i.

[3] Halliburton: Text-book of Chemical Physiology.

place in an animal cell; the electro-motive source of the current is at the zinc; in cell or tissue nutrition a similar electro-motive source exists at the seat of active chemical exchange; as in the case of zinc and its electrolyte, so with the cell or cells and its or their electrolyte of blood or lymph, chemical affinity is transformed into the electric form of energy and a current appears. In the artificial battery we term it a galvanic current, in the animal battery we recognize it under the familiar title of animal electricity: there is practically no difference between the two except that the one is an artificial and the other a natural couple or battery. My plan of electrical treatment proposes to pit the artificial against the natural battery, just as one primary battery might be pitted against another. We may represent the parallel by the four following diagrams, illustrative of an equal number of possible treatments:

Fig 1

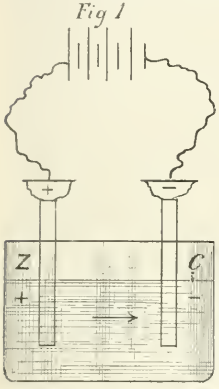

FIG. 1.—Metabolism or Chemical Exchanges Excessive. A + pole applied to the zinc augments the oxidation of the zinc, destroys it; applied to living tissue augments metabolism, augments disease.

Fig 2

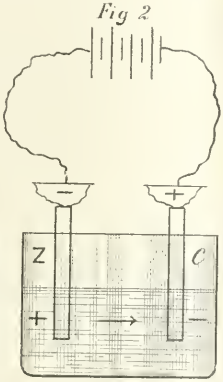

FIG. 2.—Metabolism or Chemical Exchanges Excessive.—A − pole applied to the zinc diminishes the oxidation of the zinc, restores it; applied to living tissue diminishes metabolism, restores tissue, cures disease.

Fig 3

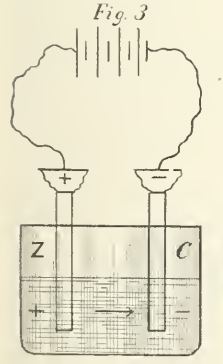

FIG. 3.—Metabolism or Chemical Exchanges Deficient. A + pole applied to the zinc augments oxidation of the zinc; applied to living tissue augments metabolism, cures disease.

Fig 4

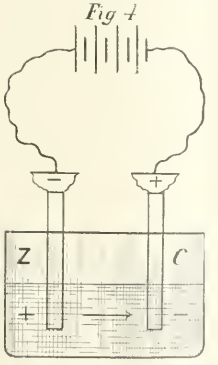

FIG. 4.—Metabolism or Chemical Exchanges Deficient. A − pole applied to zinc diminishes the oxidation of the zinc; applied to living tissue diminishes metabolism, augments disease.

In Fig. 3 the chemical exchanges are weak, but an applied + pole makes them stronger. In Fig. 4 the chemical exchanges are similarly weak, and a − pole makes them weaker.

If Figs. 1, 2, 3, and 4 be assumed to represent batteries applied to galvanic couples, it will be found that the large and applied battery, indicated by the conventional zinc-carbon characters, will affect the zinc of the couples in Figs. 1 and 3, reversely to Figs. 2 and 4. In Figs. 1 and 3 the zincs will be destroyed, the normal action of the couples will be augmented; in Figs. 2 and 4 the destruction of the zinc will be arrested, and not only arrested, but restored. And were the oxidation products in Figs. 1 and 3 insoluble and stationary, as in the case of two lead plates, we should have a storage-battery effect upon disconnecting our charging poles.

My theory, from an electro-therapeutic standpoint, is that the above laboratory experiment is repeatable within the human body, that similar effects to these above described are produced upon the chemical exchanges incident to the metabolism of a given focus of disease in a living tissue, and that to palliate or cure the disease the physician must first decide upon the pathological nature of the condition—whether the processes of nutrition of the part are excessive or deficient, and from one or the other standpoint apply an electrical polarity which shall, (*a*) diminish the chemical exchanges, or even reverse them, and thus restore and rebuild the tissue—the negative pole; (*b*) augment the chemical exchanges (disease)—the positive pole.

Having now established the fact that there are demonstrable electro-motive sources and electric currents in the human body, and referred to the probability of there being an infinitely greater number, owing to the chemical and physical relation of the parts, active but not easily demonstrable, both of which, actual and possible are initial foci of normal and morbid processes, and that these foci may serve as guides by reason of their electro-positivity to applying curative extraneous currents, it should at this place be made clear that the applied currents and polarities have the power of effecting in the intrapolar region those alterations of abnormal metabolism (chemical exchanges) which we desire them to effect. This mere physical fact is best established by a quotation from the distinguished physicist, Dr. Oliver J. Lodge, as follows:

"It may be asked, if the atoms in each molecule cling together by their electrostatic attractions, and there are an enormous number of atoms between two electrodes, how comes it that a feeble electro-motive force can pull them apart and effect decomposition; moreover, how can the electro-motive force needed to effect decomposition help varying directly with the thickness of fluid between the plates? It does not depend upon anything of the kind; the length of liquid between the electrodes is absolutely immaterial. This proves that throughout the main thickness of liquid no atoms are torn asunder at all. Probably they frequently change partners, one pair of atoms not always remaining united, but occasionaliy getting separated and re-combined with other individuals. During these interchanges there must be moments of semi-freedom during which the atoms are amenable to the slightest directive tendency, and it is probably these moments that the applied electro-motive force makes use of.

"The reality of such a state of continual interchange between molecules has been forced upon chemists by the facts of double decomposition. Such a fact is the interchange of atoms between strongly combined salts, when their solutions are mixed, so as to form very much weaker compounds, the proof that such compounds are formed being very clear in the case when they happen to be insoluble. The fact that a precipitate is formed whenever it is insoluble enough really proves that some small quantity of the corresponding compound is always formed in every case, whether it happens to be insoluble or not.

"The state of continual interchange results in a perfect sensibility to the migratory tendency of extremely weak forces, so that even the faintest trace of an electro-motive force is able to affect the charged atoms, on the average assisting the positive atoms down the slope of potential, and the negative atoms up the slope."

The fact that the most infinitesimal force is sufficient to effect its due quota of decomposition has been proved most clearly and decisively by the experiments of Helm-

holtz. We may not, therefore, doubt the power of our medical currents to effect chemical changes in the intrapolar region.

I have followed the general argument to what seems to me to be its legitimate conclusions, regardless of any preconceived idea as to treatment now in vogue. I am well aware that to follow this theory in practice will in numerous instances conflict with classical directions, while in other instances it harmonizes with results arrived at empirically. There is, at least, one satisfaction, it brings into prominence the fundamental basis of all intelligent therapeutics, and that is physiology and pathology.

And, in thus bringing forward a strictly chemico-biological electro-therapeutics, and its attendant index, polarity, I do not ignore the ordinary physiological effects of the continuous current, but I believe that electrochemical physiology may yet reach a stage of advance where these effects may be explained by the chemico-biological reactions occasioned in the intra-polar region by the electric energy. It is in line with this view that I have ventured these suggestions.

And though this study of intrapolar effects may suffer modifications on further experience, I believe that its main features will be found to hold good. These are that: 1. Disease exhibits polarity. 2. That this polarity may be augmented or counteracted by an applied current, and thus the disease be augmented or counteracted; and one result may be that the future electro-therapeutist will, by delicate tests, ascertain the polarity of the part to be treated by electricity, just as the chemist ascertains by litmus-paper whether his solution is acid or alkaline. 3. That should this polarity be thought to be due to other causes (circulation of fluids, osmosis, etc.), it may still afford a guide to electric treatment, by means of which counter or similar applied polarities may counteract or aid the causes, and thus counteract or aid morbid processes. Witness the antagonistic relations of Porret's and Quincke's phenomena.[1] 4. That this index of polarity may provide an invariable guide to treatment, and that thus electro-therapeutics may be reduced to an exact science.

II. Electro-Physiology.—The process by which Nature elaborates living tissue and by which the energy in food is converted into work, is of transcendent interest to the physician and to the physiologist. It is here suggested that the process is primarily through the medium of electricity, and not through the medium of heat.

Very little is as yet known concerning the molecular changes which occur during activity of either muscular or nerve tissue. Each undergoes physical and chemical changes. The physical changes of the muscle are a change of form, a rise in temperature, and a change in electric polarity (the contracted muscle is negative to the uncontracted); the most important chemical change is an acid reaction. The only known physical change which is associated with the activity of nervous substance is an electrical one (negative oscillation), and the only known chemical change an increase of acidity, as in muscular activity. Since so little is actually known, there has been, and is, ample opportunity for speculation.

Hermann, finding that no free oxygen is obtainable from muscle, concludes that complex chemical substances are formed in the muscle, and on contraction are decomposed; the muscular contraction is not due to direct oxidation, but the carbonic anhydride formed, as an end product, comes from the decomposition of this complex substance, which he terms inogen. Thus, though the chemical changes that take place appear as if due to oxidation, the oxygen is really set free from a prior combination. Bernstein refers the activity which results in muscular contraction not to the disdiaclasts themselves, but to the interstitial substance. He supposes each tagma to possess a positive polarity at its equator and a negative at its poles, and that it is depolarized at the moment of excitation. Collected at the pole is oxygen, and at the equator a carbohydrate, viz., oxidizing and oxidizable material; upon the union of the two there is synchronously a chemical explosion—heat and electrical change; that is to say, the sudden oxidation gives rise to the three functional characteristics of contracting muscle, motion, heat, and electricity.

[1] Ganot's Physics.

Concerning this theory Dr. Burdon-Sanderson, as quoted by Halliburton, remarks, "This view of the molecular structure of muscular protoplasm is in entire accordance with the theory of Pflüger, and with Engelmann's scheme of muscular structure. . . . It admits of being harmonized with the fundamental facts of muscle-electricity, namely, that cut surfaces are negative to sound surfaces, and excited parts to inactive, and it is not impossible to regard the three phenomena (chemical explosion, sudden electrical change, and change of form) as all manifestations of one and the same process—as products of the same mechanism."

A theory is here offered which assumes that the oxidation going on in living organisms goes on in protoplasmic parts of the tissue, organized into voltaic couples, producing primarily only heat and electricity in proportions varying with the adaptability of these parts to produce more or less of one or of the other, according to conditions of circuit, and that the electro-motive force thus generated forms at the negative element of the couple various complex chemical compounds whose decomposition produces not only physiological function, but is a second source of heat, and sets up the "current of action" or "negative oscillation." The primary electro-motive force corresponds to the "current of repose" of nerve and muscle, and it is this primary current which in a previous section of this paper, I have proposed to use as an index and guide by means of which to apply a similar or counter-current, and thus to augment or diminish it, and as a consequence, augment or diminish the nutritive chemical exchanges of health or disease which generates it.

In the electro-physiological theory here proposed, the course of events would be: chemical affinity of katabolism in living organisms undergoes metamorphosis into heat and into electricity; the electricity sets up a second and local chemical reaction, which in turn, upon decomposition, undergoes metamorphosis into motion or change of form of the part (muscular contraction), action of nervous substance (possibly again change of form), secretion (elaboration of chemical products), and electro-motive force, as in actual evidence in negative oscillation. It has often been maintained that physiological function was a direct transformation of chemical energy into function, due to the combinations of oxygen with the tissue; the theory now outlined implies that function is a transformation of chemical energy into function, due to the decomposition of complex chemical substances primarily formed by the electric action incident to katabolism. It assumes that the electro-motive force primarily generated by the body actually does the work which makes function possible. Heat, the other initial product of oxidation, is concerned in warming the water in food, in warming the air in respiration, is evaporated in the lungs by radiation and evaporation at the skin, and need not here be further considered. Bertholon has classified chemical combinations as exothermic and endothermic, according as heat is evolved or absorbed during the reaction. We will extend this classification to the evolution and the absorption of electricity, viz., to a capacity for absorbing energy which may under proper conditions be transformed into electro-motive force (as well as change of form and heat). That such an analogy is allowable is deduced from facts like the following: If one gramme of zinc be dissolved in sulphuric acid, 1,670 heat units are set free; but it is also true that if the solution take place in a voltaic cell the evolved energy takes the form of an elec-

tric current, and 2,973 coulombs are set free.[1] We may, therefore, perhaps be permitted to coin the words exo-electric and endoelectric reactions, for whether the energy set free or absorbed during chemical reactions take the form of heat or electricity would seem to depend upon the mere mechanical arrangement of the chemical substances involved in the reaction.

An example of an exothermic reaction is $H_2 + Cl_2 = (HCl)_2 + 44{,}000$ water gramme degrees, *i.e.*, heat (or electricity) is set free. But the reaction is endothermic in the instance $H_2 + I_2 = (HI)_2 - 3{,}060$ water gramme degrees, where heat (or electricity) is absorbed; or, as in hydrogen peroxide, $(H_2O)_2 + O_2 = (H_2O_2)_2 - 44{,}000$ water gramme degrees.[2]

It is obvious that the production of hydrogen peroxide absorbs a large amount of heat or electricity, and would set free an equally large amount of heat, or were the voltaic cell conditions established, of electricity, instead of heat.

Similar reactions may be supposed to take place in living tissue. In the ordinary reaction outside of the body, $Zn + O = Zn\,O +$ water gramme degrees, heat (or electricity) is set free. Within the body, the principal substances involved in the reaction are carbon, hydrogen, nitrogen, oxygen, and sulphur, which we may term briefly CHNOS compounds, in whole or in part, using these letters merely as a symbol representative of the vast variety of actual combinations.

Negative Oscillation.—To carry out our parallel to what takes place in an artificial cell, we will suppose that protoplasmic parts of the tissue have the voltaic arrangement, and that oxygen attacks the positive element, while hydrogen is directed to the negative element. The reaction is now supposed to be endothermic, and will read, $H + CHNOS = HCHNOS -$ water gramme degrees, heat (or electricity) is absorbed. We have now an unstable or explosive proteid compound at the negative element, which when it is decomposed sets free heat, or, since the voltaic arrangement exists, electricity. We may, for instance, suppose that a neural impulse causes the decomposition of this unstable compound, the electricity set free will have a direction opposite to the current which caused the combination, it will temporarily oppose and thus diminish or arrest this current, and we shall have developed the "negative oscillation" of Du Bois-Reymond, or the "current of action" of Schiff, a current, supposed by the former to be due to a weakening of the current of repose, and demonstrated by the latter to be a distinct current in an opposite direction to the current of repose, and due to functional activity. The explanation, as above given, would maintain that the negative oscillation is a distinct current, and a result of the performance of function, and the product, not of combination, but of decomposition of chemical substances.

Referring to the instability of the class of chemical compounds here referred to, Barker[3] says: "In accordance with the law that the tendency of the energy of a system is always toward a minimum, it is found that substances like hydrogen iodide, hydrogen peroxide, cyanogen, acetylene, nitrogen chloride, and the oxides of nitrogen and chlorine, all of which are formed from their constituents with absorption of heat—by endothermic reactions—are more or less unstable; being either spontaneously decomposable and even explosive, like nitrogen chloride and the chlorine oxides, or readily undergoing changes by slight external causes; but in all cases evolving heat by their decomposition. Carbon-disulphide, for example, is an endothermic compound; and Thorpe has recently shown that the shock of mercuric fulminate exploded in its vapor, decomposes it, depositing both carbon and sulphur. While, therefore, the formation of an endothermic substance cannot take place without the aid of outside energy, so, on the other hand, the decomposition of an exothermic substance cannot occur without this aid. An exothermic compound is therefore stable."

[1] Barker's Chemistry, 1891. [2] Ibid.
[3] Barker: Text-book of Elementary Chemistry, p. 77.

Endothermic compounds are not known in the usual voltaic cells, because CHO or CHNOS depolarizers are never used. But hydrogen might form on meeting CHNOS at the negative plate such an explosive compound, whose explosion or decomposition resulted in function. For, even in voltaic cells composed of metallic elements, the oxygen and hydrogen evolved at the two plates are in a nascent state, and exist at the plates, not in a free state, but in combination with the metals. This must be equally true of a protoplasmic voltaic cell, and we may thus have formed at the negative element, any combination of CHNOS of which hydrogen forms one constituent, as well as other compounds from which hydrogen has removed an oxygen atom.

We may represent a hypothetical, protoplasmic, voltaic arrangement and some of its reactions in symbols as follows, indicating in the first line a parallel to a zinc-copper cell. The reaction at the negative element is endothermic and endoelectric.

1.	2.	3.	4.
Zinc + O.	O separated from H_2.	H_2 + depolarizer.	Copper.
Protoplasm + O.	" separated from H_2.	H_2 + CHNOS.	Protoplasm.
Combination.	Decomposition.	Combination.	"
Energy set free.	Energy absorbed.	Energy absorbed.	"
Heat, Electricity.	.....	.....	"
Current of repose.			

It is the decomposition of the H_2 + CHNOS compound which produces the phenomena of functional activity, viz., nerve, muscle, and glandular action, and the current of action, viz.:

1.	2.	3.	4.
Protoplasm.	.....	H_2 + CHNOS, Decomposition, Electricity, Heat, Negative Oscillation or Current of Action, Function.	Protoplasm.

In the first tabulated reaction, the heat set free is detected and measured in the usual manner; the electricity or electro-motive force is evidenced by the signs of the current of repose, *but will give but slight evidence of its existence, since its energy is expended in the formation of the H_2 + CHNOS compound.* The heat and electricity are two prime and direct energies set free by oxidation, but all that relates to function is entirely the result of work first and primarily done by electricity. Thus, no exhibition of functional activity can be the result of primary oxidation.

This theory would claim that the inogen of Hermann, or complex chemical substances similar to it, is formed by electric action in muscle, and that all function was due to the explosion of substances also formed by electric action. We should thus have a muscle explosion, a nerve-cell explosion, a glandular or secretory explosion, or decomposition of combinations which were endothermic and endoelectric, and, as a consequence, endowed with the capacity of setting free their potential energies. Katabolism would be exoelectric; anabolism, endoelectric.

A tabulated form of description may perhaps outline these general points more clearly.

The Work of a Living Animal Organism.

- Primarily, by katabolism.
  - *a.* Heat, which undergoes no further transformation.
  - *b.* Electro-motive force, current electricity; detected by the current of repose of nerve and muscle, and occupied in storing chemical energy for purposes of function in muscle, nerve, and gland.
- Secondarily, or upon the exercise of function.
  - 1. In contraction of muscle.
    - *a.* Heat, secondary.
    - *b.* Electricity, current of action.
    - *c.* Change of form and mechanical work.
  - 2. In nervous impulses and functions of nervous substance.
    - *a.* Heat, secondary.
    - *b.* Electricity, current of action.
    - *c.* All action of nerve substance.
  - 3. In glandular activity.
    - *a.* Heat, secondary.
    - *b.* Electricity, current of action.
    - *c.* Secretion.

Thus, both electricity and heat are due to two sources, primarily to chemical combination (exothermic and exo-electric compounds), secondarily to chemical decomposition (endothermic and endoelectric compounds), the primary electricity storing up the energy which makes function possible, the secondary electricity being merely an accompaniment of function, and function itself would be a simple metamorphosis of the chemical energy of decomposition.

The view that electricity may act as the directing force which shall store up chemical energy which may again be liberated as energy, is exemplified in the modern storage or secondary battery. But the parallel is no more than a general one to illustrate the simple fact. The view here advanced, that a primary cell may store chemical energy at its negative element finds a more exact parallel in the polarization of primary cells. The hydrogen may be said to form a chemical compound, viz., the hydride of copper at the negative element of a zinc-carbon couple. Its initial electro-motive force is progressively weakened by the counter electro-motive force of the hydride of copper, until soon its action ceases. The two electro-motive forces are equally balanced.

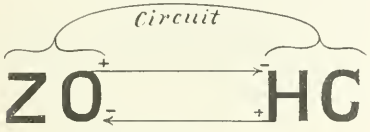

Fig. 5.—Balanced Electro-motive Force.

The hydride of copper, in forming, sets free electric energy, which flows in an opposite direction to the current which determines its combination. And did exactly this same thing take place in the protoplasmic voltaic elements I have supposed to exist, that is to say, if in the formation of the compounds which correspond to the hydride of copper, energy were set free (exothermic, exo-electric), the action of the protoplasmic couple, like that of the metallic voltaic couple, would come to a standstill.

It is at this point in the parallel that I invoke the fact of endothermic combination, or a chemical combination accompanied not by the liberation of energy, but by its absorption. Our knowledge of such combinations is due to the distinguished *savant*, Berthelot. Wurtz and Tomassi, while denying exo- and endo-thermic reactions, admit of a prior atomic combination corresponding to Berthelot's endothermic ones, but claiming that the final result is exothermic and not endothermic. We may thus validly claim an endothermic chemical arrangement of molecules at the negative element. It is this endothermic arrangement or capacity of new compounds to be formed with the absortion of heat which enables us to conceive of the building up in protoplasmic materials formed into voltaic couples, of compounds of hydrogen with the other elements of protoplasm, viz: carbon, oxygen, nitrogen, and sulphur, which are absorbers of energy. And it is these newly-formed compounds which I would claim may be the source upon their being decomposed, of a counter electro-motive force, similar in kind to that of ordinary polarization currents but differing in that they are not *continuously* counter, but only so at the moment of final explosion or decomposition. The fact that such combinations are endothermic, or absorbers of energy, permits of their formation; were they exothermic, or releasers of energy, they would bring the action of the couple to a standstill. The decomposition of such endothermic compounds releases energy and is a simple act of transformation of chemical energy into heat, electricity (current of action), and physiological function, viz: muscular contraction, nerve action, and secretion.

Summary.—1. The mutual relations of the two elements and the electrolyte of an artificial voltaic cell are also the mutual relations of protoplasmic parts of living organisms during the process of living. *a.* The oxidation of the positive plate of the cell (the zinc) corresponds to the destructive or katabolic chemical exchanges producing waste products—carbonic acid, water, etc., and liberating energy. *b.* The hydrogen or other bases acting at the negative plate correspond to the constructive or anabolic chemical exchanges, and store energy. *c.* The decomposition of the electrolyte corresponds to the decomposition of the animal electrolyte (blood, lymph, and other fluids). *d.* Oxygen and hydrogen are referred to not as the only reaction agents, but also as types of their congeners engaged in the complex chemical exchanges of living organisms.

2. The initial action of the protoplasmic voltaic arrangement is to produce only heat and electro-motive force or electricity. The latter is the "current of repose."

3. During functional rest of a given living animal area, the anabolic, constructive action or storage of energy goes on, and during functional activity the katabolic, destructive action, or releasing of energy goes on, as evidenced by their opposite polarities, positivity (in the internal circuit) being the sign of functional activity, and negativity (in the same circuit) the sign of functional rest.

4. What was a negative (anabolic) focus during rest, becomes a positive (katabolic) focus during activity. This conception of changeable electric relation is based upon the prior voltaic chemical relation, during which, in the complex chemism of living organisms, compounds of, for instance, hydrogen, carbon, nitrogen, or sulphur, are produced at the negative element with the absorption of heat. Such compounds in inorganic chemistry are termed endothermic; they are more or less unstable, easily decomposable or even spontaneously decomposable, or explosive. They evolve heat by their decomposition. They may also be termed endoelectric. In functional activity it is claimed that it is these unstable endothermic, or endoelectric substances, formed by protoplasmic voltaic action during rest, which are decomposed with production of an electric current in an opposite direction ("negative oscillation," or "current of action," and with the production of physiological function, viz.: muscular contraction, nerve action, and secretion). It may be presumed that a neural impulse, efferent or afferent, initiates the explosion. The superior power of the kathode in exciting physiological activity (including the phenomena of electrotonus) may be due to its increasing the already progressing formation of unstable or explosive material.

5. In addition to the storage material synthetized by the animal itself, and furnishing during functional activity an electro-positive plate, the principal electro-positive fuel or oxidizable tissue is furnished by the food assimilated by the animal, which food is the result of the anabolic, storage, or constructive faculty of the plant.

6. The origin and initiation of an electric current and consequent polarity cannot be from the electro-negative plate of the voltaic cell, but the current arises from the initial chemical action at the electro-positive plate and therefore the starting-point of living chemical exchanges is in the electro-positive plate—that is to say, is katabolic, oxidizing, or destructive. At the negative plate energy is stored or rendered potential. The same is true of all the energies. As a consequence, all metabolism, all chemical exchanges in living animal organisms are initially electro-positive, and if an anabolic, constructive, or electro-negative focus is found by tests it is not primary but accidental, and the result of the action of a conductively associated katabolic or oxidizing positive plate.

7. It follows, that morbid metabolism, constructive or destructive, is primarily electro-positive.

8. This invariable focal positivity provides an accurate guide to medical treatment by electricity, for the morbid

tissue focus itself may be regarded in the same light as an artificial voltaic couple. The reactions following may be experimentally demonstrated upon an artificial cell.

9. Morbid metabolism may be divided into (*a*) excessive chemical exchanges; (*b*) deficient chemical exchanges. In over-activity of the chemical exchanges (*a*) an applied positive pole will increase the activity, *i.e.*, augment the disease; (*b*) an applied negative pole will diminish the activity, *i.e.*, palliate or cure. In under-activity (*a*) an applied positive pole will increase the activity, *i.e.*, palliate or cure; (*b*) an applied negative pole will diminish the activity, *i.e.*, augment the disease. Two directions only are open for curative treatment: in over-activity the negative pole palliates or cures; in under-activity the positive pole palliates or cures.

10. If an electro-negative focus (here held to be secondary and incidental) is thought to be most desirable to be treated, the polarities indicated must be reversed. This theory implies that vital processes are electrolytic and electro-synthetic, plus a directive tendency which is a mystery; it implies that the processes of living proceed according to electric laws, releasing by the electro-chemical action of oxidation, combustion, or katabolism, heat and electric energies, with the production of waste-products of excretion, and storing or rendering potential the same energies by the electro-chemical action of anabolism, with the production of formed chemical products, essential, in the case of the animal, to its specialized existence—ferments, fats, glycogen, etc. It claims as a speculative postulate that the fundamental starting-point of both release and storage of energy, of the destruction and the construction of products, of katabolism and anabolism—of, in short, metabolism—is situated at protoplasmic foci consisting of protoplasm oxidized (or similarly attacked), and the oxidizing or attacking electrolyte of the protoplasmic voltaic couples—that the protoplasmic area attacked is therefore electro-positive, and that as a consequence of this initial action at the electro-positive area or element, a secondary constructive, storing, and anabolic chemical reaction is accomplished at a protoplasmic electro-negative area or element—in short, that anabolism is secondary to, and dependent upon, the initial katabolism.

The theory also implies that the animal continually dies that it may live—that its constructive metamorphosis is initially dependent upon its destructive; and more concisely, as regards the constructive, that it is due to the chemical union of substances set free at the positive element by oxidation and allied actions, or there receiving a determining, combining direction toward the negative element, and uniting with other substances at this negative element, antecedently oxidized or not—that, in short, katabolism and anabolism are inter-allied in an electro-chemical cycle, composed of protoplasmic voltaic couples, where katabolism initiates that movement which results both in waste products and in formed products, in released energies and in stored energies, in the currents of rest and of action, and which, when it ceases, is death of the part or of the whole.

It is this katabolic beginning, signalled by focal positivity, that we may hope to influence by an applied external energy, and thus influence those life-processes that underlie it; and since this initial katabolic centre, directly or indirectly, is the source of heat, mechanical force, electric energy, and of all the other phenomena of life, normal as well as morbid, we are in a position to suggest that this electric index of demonstrable and invariable electro-positive polarity is a guide which may enable the physician to thread the labyrynth of health and disease, and to apply a counter or an aiding energy in such a manner as to affect the normal or morbid phenomena by affecting their initial and underlying chemico-biological processes. As regards electric energy, it is believed that this may be accomplished in the manner outlined.

DISORDERS OF THE EARS IN TYPHOID FEVER.[1]

By BEVERLEY ROBINSON, M.D.,

CLINICAL PROFESSOR OF MEDICINE AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

In typhoid fever patients during the acute stages of the disease, one is not apt to direct special attention to the condition of the ears. Hence, special treatment of these organs is not usually attended to. This omission is in part explained by the fact that frequently no direct complaint is made by the patient of suffering in the ears, and because no special symptoms arise which seem to necessitate local interference. Moreover, even if the patient complains occasionally of annoying sensations in the ears, these feelings are frequently regarded as entering into the natural course of the disease, and as requiring no particular solicitude or means of relief. Again, not all general practitioners of the present day, even in our large cities, are familiar with otoscopic examinations, and for this reason are too prone to neglect them unless the situation becomes imperative and such investigation of the affected organ is urgently called for. And yet we are occasionally reminded, either during the early or later stages of typhoid fever, or after convalescence has been fully established, that neglect of accurate examination and treatment of the ears of a patient suffering with typhoid fever, has proven to be highly prejudicial to these organs later on. Many a case of permanently impaired hearing could have been prevented, doubtless, by a little judicious treatment employed during the first weeks of the disease. While this statement is true, I am not prepared to say that all cases of defective hearing following this malady are due to lack of suitable treatment when the aural symptoms were first manifest, because I know too well the gravity of the general affection. I do believe, however, that the number of sufferers from chronic partial deafness, as a result of typhoid fever, would be largely diminished if more care of the ears during its course were taken at the proper time.

Fortunately, relatively few cases of absolute deafness appear to be occasioned by typhoid fever; at least, such an affirmation seems partly warranted in view of Roosa's tabular statement in the chapter on deaf-muteism in his exhaustive treatise on aural diseases. In this respect, therefore, this fever has a great advantage over the eruptive fevers, diphtheria, and acute meningitis.

We must not lose sight of the fact, in this connection, that typhoid fever is a rare disease with very young children, particularly when compared with other acute febrile diseases of childhood. This being true, we should look for cases of absolute loss of hearing following typhoid fever rather among adults than children. Now, while I have seen the hearing very seriously affected after typhoid fever, I do not remember any instances of total loss of it thus occasioned. This, to my mind, does not argue necessarily less risk to the hearing in typhoid fever than in scarlet fever, or diphtheria, but it means possibly that better care of the ears in adult life has been taken both by the physician and the patient. Be that as it may, I hold that similar care of the ears should be taken during the acute period of disease, in cases of typhoid fever, as in that of the other acute febrile disorders, in order to be constantly on the safe side with our patients. In pursuance of this plan, we avoid occasionally very distressing complications and sequelæ. Inasmuch as the avoidance of impaired hearing as a consequence of typhoid fever pertains, in some degree at least, to the treatment of the nose and pharynx, the condition of these organs should be kept in view and, when required, proper means should be instituted to ward off possible aural complications.

There can be very little question, I believe, that either as a cause, or a concomitant condition, of the aural disorders of typhoid fever, the nose and pharynx often show

[1] Read before the New York Clinical Society, at a stated meeting held April 23, 1892.

evidence of more or less hyperæmia, accompanied with inspissated and occasionally fetid secretions, which by the proper and timely use of a mild detergent, or disinfecting spray, may be quickly and favorably modified, and with relief rather than increased annoyance, to an ill patient. It cannot be doubtful that judicious interference in this manner will prevent catarrhal otitis, at times, from becoming a prominent and disquieting symptom.

In the beginning of typhoid fever, the patient often suffers from various subjective aural sensations, like buzzing, whistling, ringing, humming, which occasion more or less distress. Later on these sensations, as a rule, diminish, or disappear; occasionally, they become more intense and have a graver pathological significance. They are said by some authors to last and to be more pronounced in the more serious forms of the general disease.

Accompanying the noises in the ear, the patient may accuse more or less local pain in these organs. Whenever pain is notable, it almost invariably shows a certain amount of acute local inflammation, either of the external auditory canal, or more probably of the middle ear itself. Under these circumstances an otoscopic examination should be made. At times, impacted cerumen is the sole cause, apparently, of distress, and when this is removed from the ear, and a few subsequent syringings with warm water have been made, the local pain and distress wholly subside. On other occasions, the drum membrane is obviously acutely inflamed, and this local inflammation sufficiently accounts for the pain and tinnitus. The inflammatory condition of the drum membrane, if properly attended to, may last only a few days, getting better gradually, and never terminate by suppuration and perforation. In other instances this fortunate termination does not take place, and despite our best care one, and rarely both, membranes give way sooner or later, and the ensuing discharge is more or less prolonged.

Not always do we meet with painful sensations as an evidence of acute aural inflammation in typhoid fever, and occasionally a perforation may occur in a sudden manner, without any abnormal sensations being accused by the patient. Thus we are not put on our guard, as it were, against the impending complication. No doubt this occurrence is frequently explained by the general condition of the patient, who is already suffering from the depressing and stupefying effect of the constitutional disease upon his central nervous system, and his appreciation of sensory functional disorders is far less acute than it would be in a normal state. We must remember, in this connection, that while aural pain, inflammation, and perhaps perforation of the drum of the ear may occur in the early days of typhoid fever, yet usually it is only about the end of the second, or during the third week, or later still, that these complications arise. From what I have said in regard to the possibility of a perforation of the drum membrane occurring suddenly in typhoid fever, and after very slight, or indeed no local sensations of pain, it follows that the careful physician should frequently inspect the membrana tympani of his patients, especially after the second week of the disease and up to the time of complete convalescence, even though no painful or other abnormal sensations are accused in the ears. These examinations, in my judgment, should be made daily, or every other day. They may fortunately remain negative, but if well-marked evidences of inflammation are discovered, the proper remedial measures should be immediately instituted. If this be done and perforation of the drum should follow, or if indeed, without perforation, the hearing becomes later on permanently impaired from middle ear disease, or an affection of the labyrinth, we can feel, as careful physicians, that we have done our best to ward off or prevent such an unfortunate occurrence. According to Louis, pain in the ear may last a long while, as much as fifteen days, he says, without suppuration taking place.[1]

[1] Nouveau Dict. de Médecine et de Chirurgie Prat., t. 36, p. 639. Paris, 1884.

This, I presume, is a correct observation in some cases and in some epidemics. But in many instances, I am confident that, long before this time has elapsed, perforation of the membrane will take place unless remedial treatment be begun. In any case, I should regard the practitioner as highly culpable who neglects his patient to the point of confiding to any such happy-go-lucky method as trusting hopefully to the possibility of suppuration being delayed such a length of time, and for this reason failing to make a searching diagnosis and subsequent careful treatment of any case in which, during typhoid fever, notable pain is accused in one or both ears. Deafness to a certain degree, at least, is certainly very common during typhoid fever, and when it occurs is apt to be very persistent. In this respect we must recognize a difference between the effect of typhoid fever upon the eyes and ears, for the former are not often or seriously injured by this malady. Whenever deafness occurs, it may affect one or both ears; in the latter case, particularly, it is due either to the propagation to the Eustachian tubes of the pharyngeal catarrh, or is in part attributable "to the blunted sense perceptions incident to the action of the poison"[1] of the disease. While the impaired hearing or deafness in typhoid fever has some evident direct relationship at times with the condition of the central nervous system, yet the precise connection between the two cannot invariably be determined in any accurate manner. In the first place, this symptom is often pronounced before the stupor has become very profound; and again, the impairment of hearing goes on to almost complete deafness without our being able to determine the interdependence between this loss of function in a special sense and cerebral accidents, notably delirium. Very marked deafness in some cases apparently lends nothing to the gravity of the prognosis. It is possible, however, even in the innocent cases, that it may be in some way connected with the duration of the disease, as it has been stated by some writers, and the more marked the deafness, the longer time the typhoid fever will last. On the other hand, I cannot agree with the affirmation that deafness in typhoid fever should be regarded as a happy index in a bad case, or with Fracastor, who has accorded to it invariably a favorable significance.[2]

Deafness of both ears, according to Wilson, was at one time looked upon as a favorable symptom, but the closer investigations of more recent observers show that this opinion is no longer tenable. The probably correct explanation of this notion, formerly received, is as follows: If both ears be affected, it means as a rule a mild extension of the catarrhal process from the pharynx to the ears; if one ear be implicated, it means that the prognosis is more regretable, because the extension of the catarrh to one ear has occasioned a purulent otitis, which may be followed by grave sequelæ. Such, at all events, was the distinction made by the famous Trousseau in his Clinical Lectures,[3] and such seems to me, even at this day, to be a satisfactory solution of a time-honored belief. In this connection Murchison[4] says, "deafness is favorable when contrasted with the opposite state, or intolerance of sound, which is sometimes met with." Oppolzer, who has searched for the pathogenic conditions of the symptom deafness in typhoid fever, recognizes for it three distinct causes: the first and most frequent is the propagation of the catarrhal process from the pharynx to the Eustachian tubes; the second is, rarely, the influence of the affection of the central nervous system, incident to the profound blood dyscrasia; the third is periostitis of the middle ear. The latter pathological condition is most frequently of metastatic origin.[5]

Murchison (p. 177) recognized the difficulty at times

[1] Wilson: The Continued Fevers, p. 166. New York, 1881.

[2] "Surditas salutem portendit" (Fracastorius, 1546). "Deafness is rather a favorable symptom in typhus" (Alison, Edinburgh University Lecture, 1849, not published). These citations are taken from Murchison, and contained in a footnote on p. 177 of his treatise on Continued Fevers. B. R.

[3] T. I., p. 170. Paris, 1861. [4] On Continued Fevers, p. 177.

[5] Nouveau Dict. de Méd. et Chir., t. 36, p. 639.

of giving a satisfactory explanation of the deafness in typhoid fever. He remarks that, "it is far too common, and often too complete, to be due to accumulation of wax, or to the swelling in the fauces, and it certainly is quite independent of the administration of large doses of quinine, as suggested by Barallier." Later observations of Roosa, Hammond, Weber, Liel, and others, show emphatically that in some instances, at least, quinine is most prejudicial in its effects upon the ears, when given in large and continued doses. Quinine undoubtedly congests the drum membrane in the most marked manner, and may occasion inflammation of this organ which shall prove lasting and injurious.[1]

Orne Green[2] quotes Roosa's views and their corroboration by Kirchner with approbation, and states: "From our present knowledge, both clinical and experimental, we are justified in asserting that the action of quinine upon the ears is to produce congestion of labyrinth and tympanum, and sometimes distinct inflammation with permanent tissue changes."

In regard to the cause of deafness, "Dr. Stokes thinks that the muscles of the ear, like those of the body generally, become softened, so that they no longer maintain the conditions necessary for the proper communication of the atmospheric vibrations to the inner chambers." Murchison does not subscribe to this opinion, and adds (p. 177), "on this view it is difficult to understand the cessation of deafness with convalescence."

Otorrhœa in typhoid fever is more frequent among children than with adults, and is also more likely to be followed by some of those disastrous cerebral consequences which occasionally take place. If the internal ear becomes inflamed and suppurates, meningitis may follow. Examples of this kind are recorded or referred to by Louis,[3] Peacock,[4] Wilson,[5] and Murchison.[6]

It is also true that consecutive deafness in these cases is frequently due to labyrinthine otitis (Duplay). Caries of the petrous portion of the temporal bone has been recognized as the occasional cause of suppurative meningeal inflammation. Abscesses of the brain, either in the temporo sphenoidal lobe, or in the cerebellum, not infrequently follow a similar pathological condition. Thrombosis of the cerebral sinuses, suppuration of the mastoid cells, erysipelas and pyæmic abscesses in different organs are among the late and terrible accidents which may occur in connection with caries of the petrous portion of the temporal bone. Cases have been reported, however, in which acute suppuration of the middle ear has been attended by septic meningitis and death, and yet the autopsy showed no involvement of the temporal bone.[7] It is possible, therefore, in some cases of this kind following typhoid fever, that cerebral complications may result from the process being carried to the nervous centres through the medium of the general circulation. Apart from these complications, the middle ear, during convalescence from typhoid fever, may become the seat of interminable suppuration which finishes in rare instances by causing complete deafness. This sad sequela, when it has occurred in children of tender age, has also in a few recorded instances become the origin of deaf-muteism. This disastrous consequence may not be immediate, but may come on by degrees and slowly. Little by little, the sense of hearing disappears entirely, and in time the power of speech is also forgotten. The vocabulary, small perhaps to begin with, is gradually lost, and even before this ultimate stage is reached, the pronunciation of such words as may still be remembered becomes extremely defective. The deaf-muteism thus acquired at an early age may be complete and lasting, and the child may be unable to talk throughout the course of his life. Fortunately, however, during the past few years, and owing to a more advanced system of education for these afflicted beings, deaf-muteism should not be regarded at the present time as wholly irremediable, since, in some instances at least, speech, if not hearing, has been restored.

The frequency of aural disturbances, or aural complications, in the course or as a sequel of typhoid fever, is very difficult to determine accurately, and in any event differs with the observers, the country, and the epidemic. The statements made by different writers cannot always be satisfactorily compared with one another. First, because the histories were not always recorded under similar conditions; sometimes they were those of hospital patients, sometimes of patients seen in city practice, or they were cases of soldiers attacked with fever during an active campaign. In some instances they were adult cases, in others children only were affected.

Manifestly, these various individual or ambient conditions must, to a certain degree at least, vitiate comparisons that have been made. As regards the mere question of complication, not everyone is agreed as to the precise definition to give to the word, and in particular as applied to the ears. Finally, it is obvious that in certain epidemics aural inflammations will be more frequently met with than in others, and even in the same epidemic of typhoid fever we are apt to notice differences in this respect, at its beginning or toward its decline. According to Murchison,[1] deafness of one or both ears was noted in 20 out of 46 cases; Louis observed it in 58 of 99 cases; Barth, in 36 of 129 cases; and Jenner, in 6 of 23 fatal cases. With respect to the presence of aural complications, the following citations may be interesting: Stricker mentions 34 cases of otitis among 172 cases of typhoid fever; Jessen, out of 186 cases of typhoid fever, gets together 13 cases of suppurative median otitis; Hoffmann has been able to state in 4 instances (at the autopsy) perforation of the drum membrane in 250 cases.

It is, therefore, obviously the duty of the medical attendant in a case of typhoid fever to examine the ears occasionally with the otoscope, even though there be no complaint by the patient of pain in the ears. This duty is more imperative during and after the second week of the disease than previously, on account of the possibility of serious aural complications at this time. The obligation of the physician in this regard is not less formal, because the general condition of the patient is such as to prevent him from appreciating any local distress unless it be excessive, and because for this reason he is unable himself to sound the note of warning to the family physician. Not only should the membrana tympani be inspected, but the nose and throat must always be looked at by means of a nasal speculum, or tongue depressor with a suitable light, either daylight or that reflected with a head-mirror from a lamp or candle. Sometimes the external auditory canal is found obstructed with wax. This should always be removed in order to make the satisfactory inspection of the drum membrane, and also to get rid of an accidental cause of possible inflammation.[2]

If, after removal of the impacted cerumen, the membrana tympani is red and inflamed-looking, we must order it to be douched two or three times daily with the fountain-syringe containing water at 100 to 110° F. This is readily accomplished with a patient in a semi-recumbent posture and without wetting him, by bringing the patient near the edge of the bed and then tying a piece of rubber sheeting around the neck, so as to allow the water to run into a vessel on the floor. The addition of half a teaspoonful of bicarbonate of soda or borax to each pint of water will be useful in allaying inflammation. From

[1] Loc. cit., p. 543.
[2] Of course, I am aware that the mere existence of impacted cerumen is prima facie evidence of previous aural inflammation. There is, therefore, still more necessity to remove it, lest it cause additional disturbance.

one to two quarts of hot water must be used from the douche-bag on each occasion that the ear is irrigated. Frequently, after half a dozen washings the inflammation will have notably diminished or completely disappeared. If at the time the ear is seen to be inflamed, there is evidence of nasal or pharyngeal catarrh, I consider it advisable to make use of a mild detergent, or disinfecting spray, through the nose and into the back of the throat, twice daily for a few days. This spray may be that of Dobell, a spray formed with one of Seiler's tablets, or a solution of bichloride of mercury, 1 part to 5, 8, or 10,000, according to circumstances.

In many instances, by carrying out these simple measures during a few days, a purulent otitis may be avoided. If the drum-membrane continues to show evidences of decided inflammation, or if, indeed, pain continues as stated by the patient, it may be advisable to apply one or two leeches in front of the tragus, even though the patient's general condition might not altogether favor such treatment. Better have a little local blood-letting with a possibility of slight weakening to follow, than the advent of a complication the end of which cannot be foreseen, and may be a source of discomfort or great annoyance throughout life.

Indeed, in some instances in which the inflammation does not subside rapidly under the action of repeated douches, or in those where it is unwise seemingly, on account of great prostration of the patient, to make use of local blood letting, further "injury to the deeper parts by extension of the inflammation"[1] may be prevented by an incision through the membrana flaccida with a paracentesis knife. Frequently, great relief follows this slight operation by liberating the pent up secretions. With an unruly child, however, in order accurately to stab the drum-head and to save pain, it is indicated to give an anæsthetic. Subsequently, little or no treatment is required, except occasional douching and cleaning the ear, followed by inflation of the drums after a few days, according to Politzer's method. If suppuration has already occurred, or come upon us, as it were, unawares, despite our careful attention and watchfulness, the preceding plan of treatment is quite as necessary as in the previous case. Sometimes the suppuration will be arrested quite rapidly, and we would feel gratified by the fact, were it not that in just such instances grave disturbance is apt quickly to follow, and instead of the fact to which I refer being considered one that indicates rapid recovery, it is a symptom ominous of evil and which forebodes serious central nervous disease.

Murchison speaks in the following terms of this fact: "I have known rigors, high fever, intense headache, and delirium, and even convulsions, occur during convalescence, and cease at once on the appearance of discharge from the ear."[2]

Pyæmia and thrombosis of the internal jugular vein may result from such cases. In order to ward off these deplorable complications, trephining the mastoid process, and even opening into the lateral sinus, may become necessary. The soft tissues over the mastoid may not be much swollen and be only moderately painful on pressure. The neck in the vicinity of the process, however, is usually infiltrated and tender, and the patient may be hoarse, and experience some dysphagia. If the operation be delayed too long and pyæmia be already present the lungs and liver may offer signs of the existence of metastatic abscesses. If the mastoid process be trephined, an exit will be afforded to pent-up, cheesy, fetid-smelling pus. The opening of the lateral sinus, as in the case of Keen,[3] may be followed immediately by profuse hemorrhage, which should be arrested by means of instant plugging with iodoform gauze. If the suppuration occasioned by the otitis media continue indefinitely, and despite the use of astringent solutions of zinc, alum, etc., this condition should be treated for a while with insufflations into the drum-cavity of finely powdered boric acid. Unfortunately, this dry treatment will also at times fail to effect a permanent cure. Not only will the boric acid insufflations not invariably arrest the otorrhœa, but they may prove to be directly detrimental to the patient by interfering with proper aural drainage. Thus the pus may be dammed back in the affected ear and septicæmic symptoms may be induced. The latest and most approved method of treatment in these cases, according to some advanced aurists, is to obtain and maintain perfect drainage in the best available manner. This method, according to them, is "by excision of the membrana tympani and the two larger ossicula, or their remnants."[1] According to others, every such case "should be treated by free opening of the mastoid antrum and the establishment thereby of thorough means of irrigation and drainage; and if that should not prove sufficient, by exposure of the dura mater both above the tympanum and in the neighborhood of the lateral sinus."[2] More or less similar operations to the foregoing have been successfully performed by H. Knapp, C. J. Blake, and B A. Randall,[3] in numerous instances of mastoid disease of different origin.

In this connection, however, "it must be remembered, that considering the enormous number of people who have perforation of the drum, comparatively few die of 'brain disease,' and they will go through life, hampered it may be, yet safely and well, by the employment of the milder remedies"[4] to which I have previously referred. To prove this, permit me to read the following citation: "Among 13,000 patients treated at the Aural Clinic of the Berlin University, brain abscess was found eight times in two and one-half years. The mastoid was opened thirty-five times in the same period. One case of cerebral abscess occurred among 2,650 cases of acute suppurative otitis, with 149 operations on the mastoid; 6 chronic abscesses in 2,500 chronic suppurations of the ear, with 206 operations upon the mastoid. In the 149 acute cases in which the mastoid was opened, pachymeningitis was found 49 times; in the 206 chronic cases, 34 times. In 14 cases, thrombosis of the transverse sinus was found, usually with sepsis and pyæmia."[5]

Enough has been said, I believe, to show the great importance of my subject. In my judgment there are few more so in connection with the management of typhoid fever. A full appreciation of its gravity, and an accurate knowledge of the means which should guide our treatment, are not uncalled for.

In conclusion I would add, that, so far as I know, the aural complications of typhoid fever have never been thoroughly studied by anyone competent to observe and record these cases. By this statement, I merely mean that the general practitioner, into whose charge the patient naturally comes, does not use special instruments and is deficient in special knowledge of aural conditions when disease exists. The specialist only occasionally sees such cases when they are particularly severe, and does not follow them from day to day, as is essential to note what changes frequently occur, and what treatment is most efficient as these changes arise. Later, when the aural disease remains in the convalescent period of the fever, great damage has already taken place, and the hearing is much and permanently impaired.

My few imperfect observations, and bringing together recorded data, may have, therefore, a more than passing interest, and I only trust they will lead someone to make careful and more complete observations in a far larger number of cases than those I have been able to study.

TREATMENT OF YELLOW FEVER IN BRAZIL.

By RALPH M. WHITEHEAD, M.D.,

CHICAGO, ILL.

The treatment of yellow fever during the recent epidemic of 1891–92, in Rio de Janeiro and Santos, Brazil, has been characterized by the introduction and adoption, by a few of the more advanced Brazilian practitioners, of a more rational method of treatment than has been in use heretofore. The ill success of the old method has induced a few of them to try the more modern hydropathic measures, which have been so successful in the treatment of typhoid fever; and they have been gratified to see a greatly reduced death-rate as the result of the innovation.

Notwithstanding the fact that the pathology of the disease is but little understood, the Brazilians have not been content to treat the fever symptomatically until the light of positive knowledge shall show us a shorter way, but have made the mistake of vainly searching for some empirical remedy that would abort, or shorten, the course of the fever; ignoring the support of the patient, overlooking almost entirely the necessity of making an effort, at least, to check the vomiting, and remaining totally oblivious of the fact that a little at least may be done toward checking the suppression of urine. The results attending their methods have been more or less successful from year to year, in a direct proportion to the benevolence or malignancy of the successive epidemics.

Many different methods have been in use. The method of longest standing is that which may be called the calomel treatment, and until a few years ago it was the only treatment in vogue, and even now is extensively followed by some of the older practitioners. The mild chloride of mercury was administered in small doses to the point of salivation, and often its administration is even then not checked. What they expected to accomplish by this nobody can tell. It was given because it was deemed, empirically, to be the proper and only remedy. Of late years, however, it has been largely abandoned, and the method most generally followed is probably that of Freire, who is regarded in Brazil as authority on the subject of fevers. He advises the production of extreme cinchonism by the administration of quinine sulphate in large doses, and argues that this should be pushed to extreme limits during the stage of remission, or the second stage, and that by so doing the fever will often not advance to the third stage, or that of exacerbation, but that the temperature will fall to the normal point with the termination of the second stage; convalesence beginning immediately. Or if it does progress to the third stage, that it will not be severe, the so-called "black vomit" not appearing at all, and but very little diminution taking place in the quantity of urine excreted, and the quantity of albumin not being over ten per cent. at any time.

In the type of fever known in Brazil as "Febre amarilla benevolencia" (benign yellow fever) this plan of treatment acts very well, for the result obtained very nearly coincides with the natural clinical history of this type of fever. But as the malignancy of epidemics differs very greatly from year to year, it so happens that during some epidemics this treatment is very successful; in other seasons, however, when a more severe type of fever has prevailed, it has been very unsuccessful, and a high rate of mortality has existed. The poor success of this plan of treatment led to the adoption of certain modifications and additions, and it was proposed to induce an intense diaphoresis in conjunction with the administration of the quinine, this being continued for several days at stated intervals. The underlying idea of this treatment was that it would relieve in some measure the intense congestion of the alimentary tract, that it would stimulate the excretory powers of the skin, and thus relieve the kidneys of a part, at least, of their burden, rendering them less likely to become inflamed, and increasing the chances of the patient for recovery. Counter-irritation was maintained by sinapisms applied to the epigastrium, the calves of the legs, and the soles of the feet. Although the thirst is intense, hot drinks only were allowed, that the promotion of diaphoresis might not be interfered with. This treatment, though seemingly good in theory, has been found to be very unsatisfactory, if not positively injurious, in practice; only extremely robust constitutions are able to withstand it. The extreme weakness produced by such constant sweating, the nervous irritability generated by the heat and weight of the blankets, the restlessness from an intense thirst, in no degree quenched by the hot drinks constantly administered, added to the natural tendency of the disease to rapid emaciation and devitalization, leaving the patient in a condition so weak that he collapses from exhaustion or dies from loss of blood which is thrown from the stomach with each effort of vomiting, and which efforts the patient has no longer the power to resist.

The great mortality attending this treatment seemed to indicate that either the therapeutic indications had not been properly interpreted, or that the correct treatment to meet the indications had not been found; and especially has this seemed to be true, when we remember that yellow fever in itself is a self-limiting disease, with a tendency to result in recovery if only we are able to protect the patient from death from exhaustion. This fact has led some few practitioners to abandon this style of treatment altogether, and to manage their cases entirely upon an antipyretic and symptomatic basis. And now, in the hands of many practitioners the temperature is controlled entirely by the application of cold in some form, and we find sponging with cold water, iced water, or tepid water, as the case may indicate, graduated baths, and cold baths in frequent use. What little has been done in this line, however, has been done in the face of the greatest opposition from the Brazilian people, who still regard the use of cold water in fevers as highly injurious, and the word ice in the same connection as synonymous with sudden death.

It is better not to try to divide the treatment into stages corresponding with the stages of the disease, but to bear in mind constantly the indications for treatment, which are, to lower the temperature, to prevent vomiting, and check the extravasation of blood, to prevent the suppression of urine, to nourish and stimulate the patient.

The patient should be placed in a light and airy room, where an abundance of fresh air may be at all times found, and where ventilation is unobstructed; should be clad in a thin night-gown only, and with nothing more than a sheet and a coverlet for bed-clothing. As soon as it is possible, after the initial chill, a mild cathartic should be administered—calomel, grs. v., is usually given, and followed by castor oil, oz. j. to iv. to clear the intestinal canal of its accumulation of fæces, as constipation usually exists before an attack. As the taste of the latter drug is somewhat nauseating, and as there exists a strong tendency to vomiting from the very beginning of the attack, great difficulty is sometimes found in retaining the oil, but this difficulty can usually be obviated by floating it over a small quantity of lime- or lemon juice, which being swallowed after the oil, entirely removes the taste from the mouth.

Although the pain in the head and back, which ushers in the disease, is most excruciating, opiates must not be given. Opium and its preparations are contra-indicated by reason of the tendency to diminish the quantity of urine. An attempt at alleviation is sometimes made by the hypodermatic injection of small doses of belladonna, but usually it is of very little benefit. The temperature is best controlled by the application of cold. Sponging every four or six hours with cold or iced water has been found to be not only beneficial in reducing the temperature, but also in preventing the patients from falling into that general apathy which is characteristic of fatal cases of yellow fever, and from which it is almost impossible to arouse them, once they succumb to it. Cold and graduated

baths are superior to sponging, but are rarely attainable. An ice-cap applied at intervals to the head is very grateful to the patient. A great deal of success has also attended the practice of flushing out the colon with cold water. Not only does it act as an efficient antipyretic, but also constantly washes out the lower bowel, preventing the accumulation of the products of retrograde metamorphosis and the possible absorption of the ptomaines produced thereby, but in addition imparting a tonicity to the walls of the intestinal blood-vessels, reducing the liability to the extravasation of blood, so often the cause of death in the so-called "black vomit" and "tarry stools."

The attempt has been made to establish an intestinal antisepsis by the addition of "boric acid," "beta-naphthol," "creosote, and carbolic acid" to the clyster, but no marked results have as yet been observed. Antisepsis by way of the mouth has also been attempted, and salol, iodine, creosote, carbolic acid, have all been administered; the bichloride of mercury in minute doses has also been largely used, the so-called Sternberg's solution being given every four hours.

℞. Hydrarg. chlor. corros. ..... gr. ijss.
Sodii bicarbonatis. ..... ℥ ij.
Aquæ destillatæ. ..... q.s. ad ℥ xxxij.
M. et Sig.: One teaspoonful every four hours.

It is very questionable, however, in the minds of many, whether the result desired is obtained, and whether the administration of this remedy does not often produce more irritation to the stomach than compensating benefit is derived. No particular difference has been noticed in the clinical history of two parallel cases, in one of which it was administered and in the other not.

The control of the vomiting is the most difficult problem to be solved. And it is one of so great gravity that if its solution is not reached, the death of the patient will inevitably follow. Ice is one of the most valuable means at our command, in this connection. Small pieces of cracked ice swallowed from time to time are often successful in checking it.

Copious draughts of iced water often subserve the same purpose, and small doses of champagne, iced very cold, and repeated at frequent intervals, will at times be successful where all else fails. Often, too, on the other hand, heat will check the vomiting most successfully in those cases where it is caused by the oozing of blood through the vessel-walls into the stomach. The hot water, by checking the oozing of the blood, checks the vomiting secondarily by removing the cause. Sometimes equal parts of camphor and chloroform will exert a benificent influence.

℞. Chloroform,
Spts. camphor ..... āā ℥ j.
M. et Sig.: Give six drops in one ounce of water, every hour.

Cocaine hydrochlorate, in a menstruum of fluid magnesia, by producing a partial anæsthesia of the gastric lining, and possibly by diminishing the extravasation of blood by partially contracting the blood-vessels, is of considerable merit, and is found to be most successful in those cases which are characterized by a tendency to "black vomit."

The following is the formula for this mixture:

℞. Cocaine hydrochlorate ..... gr. j.
Fluid magnesia. ..... ℥ ij.
M. et. Sig.: Give one teaspoonful p. r. n.

Sometimes when all ingesta are immediately rejected, and the stomach evinces such extreme irritability that even water is refused, the hypodermic administration of citrate of caffeine will be effective.

℞. Caffeinæ citratis,
Sodii bicarbonatis. ..... āā ℈ ss.
Aquæ destillatæ. ..... ℥ jss.
M. et Sig.: For hypodermatic use.

Often, too, when all medicine fails to render the desired effect, it may be obtained by the application of an ice-bag or an ice-water coil to the epigastrium. It must be immediately and firmly applied with each repetition of the desire to vomit. And when this alone is ineffectual, it will sometimes be successful if used in conjunction with a simultaneous ingestion of cracked ice, iced water, or iced champagne. It sometimes happens, however, that none of the medicine or the application of cold or heat will check the vomiting, everything tried has no effect, and the patient becomes weaker and weaker until death takes place from exhaustion or loss of blood. These cases seem to be hopeless from the beginning, and no matter what may be done or tried, no reaction can be produced. In cases characterized by much extravasation of blood, the tincture of the chloride of iron is given for some time after the vomiting has been controlled.

The kidneys require close attention, for probably more fatal cases result from the suppression of the urine than from the loss of blood in "black vomit." Digitalis is usually administered from the beginning, and is usually combined with small doses of belladona, and the combination is usually effected in a menstruum of fluid magnesia, thus combining into a single preparation the medicines desired to act upon both bowels and kidneys; and it is important in this disease that such combinations should be effected, as the medicine cannot be given very frequently, as more often than not it is instantly voided, and the frequent ingestion of medicine provokes vomiting. The suppression of the urine usually commences on the third or fourth day, albumin in abundance can often be detected on the second day, and toward the termination of the fever the urine is loaded not only with albumin, but also with bile. In some atypical cases the suppression of the urine is the first symptom noticed. Such cases are always fatal. The spirit of nitrous ether, given hypodermically, seems to act successfully more often than any other diuretic, but its exhibition is usually delayed until the suppression becomes marked, digitalis being relied upon in the earlier part of the attack; as in many cases the suppression never advances to such a grave degree that it is necessary to use the spirit of nitrous ether at all. Dry cups over the kidneys will sometimes relieve in a measure the congestion. In cases marked by a rapid suppression nothing seems to be of any avail, and the constantly augmenting diminution finally gives way to total suppression, which almost invariably means death, one or two cases only being on record in which recovery has followed a total suppression.

The support of the patient is a difficult matter, for the ingestion of food is contra-indicated during the first stage of the fever, and also during the last stage if the tendency to "black vomit" is strong. Food, even if retained for a short time, is not digested, and the irritation caused by its presence is so great that often it brings on almost uncontrollable vomiting. Experience has shown that no attempt at alimentation must be made until vomiting is thoroughly under control. When this end has been attained, the food must be given only in very small doses, but frequently repeated. Milk diluted with some one of the aerated waters, is usually selected, and is given at first in tablespoonful doses only. As the patient progresses toward recovery, milk-punch is allowed, followed by light soups, egg-nog, soft-boiled eggs, raw eggs with sherry or port wine, etc. Port wine is usually given from four to six times per day, for two or three weeks succeeding the establishment of convalescence. Great difficulty is experienced at first in preventing patients from eating too much, as the appetite is enormous and it seems often impossible to satisfy it.

The emaciation produced by the fever is very great and very rapid, the loss in weight sometimes amounting to as much as from twenty to forty pounds, depending upon the original weight of the individual and the severity of the attack. The duration of the disease in mild cases is from four to six days, and in severe ones eight to twelve. Adipose people lose more weight than their leaner brethren. Convalescence once established pro-

ceeds very rapidly, and as a rule, to perfect recovery; but a loss of muscular power, which is not regained for a considerable length of time, remains in nearly all cases. The jaundice needs no attention, as it usually passes away inside of two weeks without treatment.

A startling difference is observed in the mortality resulting from private and hospital practice. The death-rate of the Brazilian yellow-fever hospitals is something appalling. The treatment is almost nothing at all beyond the administration of quinine, and they are utterly destitute of the appliances necessary for the most successful treatment. They are in nearly all cases so greatly overcrowded as to interfere with proper ventilation, and the attendants (nurses they are not) are in a great many instances any person that can be picked up out of the streets, who are willing to work in a yellow-fever hospital; and they consequently know, not only nothing about nursing, but in many instances have not the faintest idea of how to perform their duties properly; and they are so few and far between that they are unable to attend to the wants of one-half their patients. A considerable portion of the time of the few attendants that they do have is taken up in removing to a side room, called "the dying-room," such patients as are deemed past recovery, that their beds may be vacated to make room for the constantly arriving train of new victims. So little attention is shown patients that several instances are known of patients making their escape from the Santa Casa da Misericordia in Santos, and not only were they not missed, but afterward, on recovering, found themselves recorded on the books of the hospital as having died, and having been buried.

At only one public hospital in Brazil has there been any attempt to introduce a better line of treatment, and that is in the Almeida Moraes at Santos, a hospital patronized and partially supported by the hospital tax on foreign shipping, and to which most of the foreigners that are attacked are now sent. Although they have no arrangements for baths, and their attendants are too few to admit of the administration of sponging or clysters (and indeed they still regard them as dangerous procedures), yet, a patient has a much better chance for his life here than in most of their hospitals, for it is situated near the sea-shore and a fine sea breeze constantly blows through the wards, keeping them always cool, and, moreover, crowding of patients is not allowed. Ice and iced water are freely dispensed to all patients, and as much attention as possible is paid to the wants of each. This alone has reduced the mortality of this hospital considerably, and the authorities pride themselves on the fact that they rarely lose an average case that comes to them in the very beginning of the attack.

This certainly is a step in the right direction, and it is to be hoped that it will extend to all the hospitals in Brazil, and that in the future we shall cease to hear of yellow fever being so frightfully fatal as it is now, and has been heretofore, in Brazil.

Earthworms and Tuberculosis.—MM. Lortet and Despeignes, in continuing some researches into the behavior of earthworms to tuberculous matter, have given additional scientific basis to the arguments advanced in favor of cremation. They have found (*Lyon Médical*, No. 29, 1892) that earthworms living in soil which contains tuberculous material bring up the bacilli to the surface. The worm-casts under such circumstances are capable of producing the most virulent tuberculosis in guinea-pigs.

A New Departure has been taken by the city government of Philadelphia with regard to sectarian medicine. The Mayor has signed a bill appointing a corps of homœopathists, consisting of one from each poor district of the city, twenty-five in all, to share, with the regular physicians previously appointed, the medical care of the city poor.

Clinical Department.

A SUCCESSFUL EXTRACTION OF A BOTTLE FROM THE BLADDER.

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

The following is an extract from the clinical records of the Mountain Side Hospital: J. D——, aged twenty-four, domestic, single; residence, Montclair, N. J.; admitted August 6, 1892. Diagnosis, foreign body in the bladder. The patient has always enjoyed good health. A year or more ago she was treated with apparent success for some uterine trouble. About five weeks before admission she pushed a small vial into her urethra. While manipulating it, she lost her hold of it, and the object slipped into her bladder. Through shame she said nothing of her mishap, until forced to do so by painful and difficult micturition, and increasing pain and soreness over the vesical region, so that walking became painful. She then consulted a doctor. An ineffectual attempt having been made to extract the foreign body, the patient was advised to come to the hospital, where she came under the care of Dr. Love, of Montclair, and the writer. After the patient had been completely anæsthetized by ether and the urethra fully dilated, the bottle was discovered by the finger lying across the lower part of the bladder. By considerable manipulation the mouth of the bottle was brought near to the proximal end of the urethra, and held there by the left index-finger pushing it against the symphysis pubis, and by strong external pressure upon the bladder. A long, slender, but strong pair of forceps was taken in the right hand and its blades gently introduced upon the left index-finger as a guide. By a lucky manœuvre one blade was slipped into the mouth of the bottle, and with its fellow on the outside gave an excellent hold. The danger of breaking the bottle was thus reduced to a minimum. By a gentle undulatory motion the foreign body was safely delivered. It was beautifully incrusted inside and out with urinary salts. It was three and one-quarter inches long and one-half inch wide at the mouth, being a little wider below. It had a rounded bottom like a ginger-ale bottle. August 13th, the patient declares herself well and desires her discharge from the hospital. She has never had any incontinence of urine, and only suffered from pain for about forty eight hours after the extraction of the foreign body. She is taking three grains of salol ter in die, and the sediment in her urine is rapidly disappearing. Her bladder has been washed out daily with a boracic acid solution (gr. 10 to ℥ j.).

EYES OF DIFFERENT COLORS.

Dr. M. D. Hubbell, of this city, writes: "While crossing the North River from the Erie Depot in company with a friend, one afternoon recently, our attention was called to a company of fresh-air children. Among them I noticed a girl of about fourteen years, whose eyes presented a most distinct contrast in pigmentation. The right eye was a dark hazel, and the left eye a moderate light blue. Both presented the utmost uniformity of pigmentation in their respective colors, and were without other noticeable blemishes, either in size, form, or shape."

A New Use for the Nickel-in-the-slot Machine.—The Paris correspondent of the *Medical Press* writes that a new departure, and one well calculated to contribute to the comfort of the working classes, is the establishment in Paris of hot-water fountains on the penny-in-the-slot principle. Seventy or eighty of these will shortly be in working order, distributed throughout the city. On introducing the requisite coin, ten litres of water, heated by a "geyser," is given forth at a minimum temperature of 140° F.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, September 3, 1892.

THE APPROACH OF CHOLERA.

THE cholera may be said now to be epidemic, or at least present, in all the seaboard cities of Northern Europe which lie in the route taken by the Russian refugees on their way to this country and England. Thus cases are reported in Hamburg, Bremen, Rotterdam, Antwerp, Havre, Dundee, Liverpool, and Glasgow, and other places, such as Berlin and possibly London, have become infected secondarily from these centres. Hamburg may be said to be the chief of these distributing centres, and from that city travellers have carried the disease to many of the places above mentioned as well as elsewhere. In Russia the epidemic is nearly stationary.

The first infected ship to appear at this port was the Moravia. She left Hamburg on August 18th, the day cholera was discovered in that city, and arrived here on the 31st. Twenty-two passengers had died during the voyage. There is, however, no cause for apprehension that the disease will get further than quarantine. All the ordinary approaches to this country are fairly well guarded, but there are other ways than by the Atlantic seaports and on the European liners, that the disease may creep in. One of these ways is by the West Indies and the Spanish Main. Vessels from Hamburg and other European ports sail regularly to Havana, Port-au-Prince, San Domingo City, La Guayra, and Vera Cruz, which places are also in regular steam communication with various points on our Atlantic and Gulf coasts, and it is not impossible that the disease may reach this country by some such round-about route, as it has before. Indeed, it is already reported to have appeared in Venezuela, where the revolution interferes with all enforcement of sanitary measures. Canada is also a weak spot, as the quarantine facilities there are admittedly defective. However, the Dominion authorities are fully alive to their peril, and forewarned is forearmed. The Hamburg-American line has given notice that it will discontinue its emigrant service to New York until the cholera has ceased on the other side, and it is likely that the other transatlantic lines will do the same. We need not feel especially grateful to their managers on account of this decision, however, as it was arrived at through no unusual consideration for the health of this country, but chiefly because the companies lose money when their vessels are subjected to long detention at quarantine.

Should it happen that the disease eludes the watchfulness of the quarantine officials, or enters the city by rail from other less efficiently protected ports, we are at least prepared to meet it as we never were before. The city is clean, there is an abundant supply of water that is not likely to become contaminated with cholera germs, and there is good drainage. With all these conditions in their favor, the sanitary authorities here ought to, and we doubt not will, be able to cope with the disease should it come, and keep it well within bounds. There is, in this city at least, no present cause for alarm. Prudence calls for scrupulous attention to the details of public and private hygiene, but that is all.

TREATMENT OF ALOPECIA AREATA.

IN an interesting article appearing in the *Annales de Dermatologie et de Syphiligraphie* for July, 1892, Dr. Raymond describes a mode of treatment of this obstinate affection which has been of good service in his hands. The therapeutic indications, he says, are three in number: 1, To bring about a rapid reproduction of the hair; 2, to prevent auto-infection, and to remove the dangers of transmission of the disease to others; 3, to prevent recurrences. The variety of the alopecia, the date of its appearance, and the length of preceding treatment must be taken into account in each case. Lotions of corrosive sublimate, iodized collodion, and tincture of iodine, as well as stimulating lotions, have given the author only unsatisfactory results. The method of treatment by intradermic injections, advised by Dr. Moty, is open to two serious objections: the extension of the patch during treatment, and the possibility of new patches appearing before the first is cured. The injections do not arrest the falling of the hair, and in two cases the author saw a new growth beginning on one side of the plaque while the hair was falling upon the opposite side; the area of baldness continued to extend, and in three instances new patches appeared during the treatment.

On the whole, this method does not appear to the author to present enough advantages to compensate for the inconveniences. He does not believe with Dr. Moty that the antiseptic substances thus injected act upon the probable parasites of the disease located within the tissues, but thinks rather that the action is one of revulsion. The same effects can be obtained with a one per cent. phenic acid solution. Following out the idea that these intradermic injections act rather by revulsion than by direct effect upon micro-organisms, the author has employed injections of simple water under which the patch becomes reddened just as after the use of corrosive sublimate. His observations have not yet been concluded, but the water produces no pain, and after the seventh injection hair begins to grow again just as it did in a number of cases after the seventh injection of corrosive sublimate or other antiseptic.

The two methods which have given the best results are that of Dr. Busquet and of the author himself. The former consists in the local use of tincture of cinnamon. This has the advantage that it can be applied by the patients themselves, and its employment has seemed to shorten the duration of the disease. Dr. Raymond's method is founded upon the view that continuous excitation of the skin is required to awaken the vitality of the

hair-bulb. To effect this the scalp is to be shaved, and twice a week thoroughly washed with some antiseptic soap. Each morning it must be rubbed with a mixture composed of bichloride of mercury, 0.5, tincture of cantharides. 25.0, balsam of Fioravanti (a preparation of the French codex), 50.0, and cologne water, 150.0 parts. The bare spots are to have an additional friction with the same solution applied by means of a stiff paint-brush. At night the patches should be rubbed in the same manner with a mixture containing 2 parts of salicylic acid, 10 of beta-naphthol, and 15 of crystallizable acetic acid, in 100 parts of castor oil. In all cases thus treated, the writer claims that the new growth of hair has appeared within the first month.

Generalized alopecias, in which possibly all the hairs of the body are lost, are looked upon as tropho-neurotic, and are not benefited by this mode of treatment.

THE MICROBE OF SOFT CHANCRE.

Drs. Quinquaud and Nicolle reported, at a meeting of the French Society of Dermatology and Syphilography, held July 7, 1892, that they had succeeded in coloring by a special method a bacillus which they believed to be the specific microbe of chancroid, and to be identical with that described by Unna. Their method, which they consider preferable to others heretofore employed, consists in coloring the sections with phenicated methyl blue and hydrates, and clearing them up with aniline oil mixed with xylol. A special form of bacillus is then seen arranged in very numerous and very long twisted chains, occupying the tissue of the excised chancroid. These little cordons are located in the lymph spaces and outside the cells. The aspect of one of the sections is said to be so very characteristic, that a diagnosis may be made at the first glance. The bacillus is not colored by the Gram method, nor by the ordinary process of Kühne. Culture trials have been made without success, and the results of inoculation experiments in animals have also been negative.

A POOR TIME FOR CRITICISM.

A press despatch from New Orleans credits a former president of the Louisiana State Board of Health with some very injudicious as well as, in part at least, unfounded utterances in disparagement of quarantine on the Atlantic coast. Among other things he is reported to have said :

"As for New York and other ports along the Atlantic seaboard, excepting Charleston, their methods and equipments are wofully inadequate to their necessities. They are, in fact, as revealed by this emergency, mere political office-rewarding stations, whose methods are a perfunctory make-believe to hoodwink the public with a show of importance, while in fact they lack every essential of scientific requirement and trustworthiness."

This statement is so misleading, and so malicious as well, that we are inclined to believe the gentleman in New Orleans has been incorrectly reported. But whether he has or not, the present is not the time to excite distrust and suspicion of those charged with the defence of our country against this foreign invasion. A very grave danger threatens us, and it is the duty of everyone to do what he can to aid those who are charged with the task of averting it. It is now too late to make any change in methods or men at our own or other quarantine stations, were it possible or desirable to do so. They are now undergoing a severe test, and if they succeed in keeping out cholera, let them receive the credit that will be their due, whatever sanitary system or whatever political party may derive advantage therefrom. We believe the system of maritime sanitation in use at the quarantine stations of the Mississippi River is a good one, but we cannot agree with the gentleman above quoted when he asserts that the only possible means of escape will be through "extraordinary efforts in the immediate enforcement of rational and scientific methods of defence, as embraced in our own (the Louisiana) quarantine system."

SUN-SPOTS AND INSANITY.

Some of the daily papers have expressed the opinion that, if careful observation were made, it would probably be found that insanity and nervous affections prevail most during periods of great magnetic disturbance. This opinion was the result of observing reports of cases of sudden insanity during the sun-spot maximum of 1883, 1884, and 1885, and of the present very marked disturbance of the sun and the magnetic force.

It was suggested that insanity is a heliocy rather than a lunacy. Facts so far show only that insanity is more frequent in the hot weather of summer and least frequent in winter. Lunatics seem rather more restless and insomnic during full moon. Both Arndt and Griesinger note that during the syzygies there is especial excitement and, among the epileptics, more fits.

Congress for the Study of Tuberculosis.—The following questions have been proposed for discussion at the third session of this Congress, to be held in Paris in July, 1893 : 1. The respective *rôles* of contagion and of heredity in the propagation of tuberculosis ; 2, Infectious diseases as predisposing causes of tuberculosis, and the influence of certain of them in the localization of the disease, as of gonorrhœa in testicular tuberculosis or of influenza in the pulmonary form ; 3, Periods of inactivity of tuberculosis, their duration, the means of recognizing them and of detecting the signs of their cessation, and the causes of their cessation ; 4, The modes of diagnosis of bovine tuberculosis, and especially concerning the value in this regard of injections of tuberculin ; 5, The dangers which may arise from the inhumation of those dead of tuberculosis, the opportuneness of substituting cremation, and the necessity of destroying the bacilli in the bodies of those dying from tuberculosis ; 6, New methods of prophylaxis and treatment based upon etiology ; 7, The utility of making meat inspection a regular practice everywhere. A prize of three thousand francs ($600) is offered for the best essay upon "The Means of Diagnosis of Latent Tuberculosis before the Appearance, or after the Cure, of the Declared Disease." The essay must be written in French, and sent to Dr. L. H. Petit, 76 Rue de Seine, Paris, prior to April 1, 1893. The essay is to be accompanied by a sealed envelope containing the name and address of the author.

News of the Week.

Cholera and Yellow Fever in Venezuela.—It is reported by way of Panama that the cholera has broken out in Venezuela. The long-continued rebellion, it is said, has caused sanitary conditions to be neglected, and this, together with the impure water-supply and the scarcity of food, is said to have aided the disease in its progress after its introduction. Yellow fever is also reported to be still epidemic in Venezuela, especially so among the soldiers of both the Government and the revolutionary forces. The mortality among the troops is very great.

Texas Fever.—Some forty cases of this disease have been discovered among cattle in the stock yards in this city. The disease is said to have been imported by apparently healthy cattle from Texas, and to have been communicated to less hardy milch-cows from this region. All the affected animals have been killed.

Berlin Cholera Regulations.—The Ministry of Ecclesiastical, Educational, and Medical Affairs in Prussia has published the following set of instructions as to the course to be followed in case of an epidemic of cholera: "1. The virus of cholera exists in the evacuations of the patients, and can be transferred with them to other persons, and can also be transported in articles of the most varied character. Such things are, for instance, linen, clothes, articles of food, water, milk, and other drinks; and if even the slightest traces of the evacuations, not perceptible to the natural senses, exist on or in them, the pestilence can spread. 2. The contagion may easily be carried, therefore, from place to place by persons who are or have been ill of cholera, or have come into contact with such, and who leave their places of residence in order, as they think, to escape the danger that threatens them there. This is all the more to be warned against, as, on the one hand, one may be already infected before departure, and, on the other, one can protect one's self better at home than when travelling, by taking the following precautions: 3. People from places where cholera exists should not be received into houses. As soon as cases of cholera have occurred in a place, persons coming from it must be regarded as possible bearers of the germ of the disease. 4. Lead as regular a life as possible. Experience teaches that all disturbances of digestion make one specially susceptible to cholera. Be on guard, therefore, against whatever can produce such disturbances, such as excessive eating and drinking and the use of indigestible foods. Avoid especially whatever causes diarrhœa or irritates the stomach. In case of diarrhœa consult a doctor at once. 5. Eat and drink nothing coming from a house where cholera is present. Things by which the disease can easily be transmitted—for instance, fruit, vegetables, milk, butter, fresh cheese—must be avoided or taken only after being boiled. Especially the drinking of unboiled milk is to be avoided. 6. All water which may be polluted by excrement, urine, kitchen refuse, or other dirt, must be most rigorously avoided. Water taken from the ground under inhabited places, or from swamps, ponds, drains, or rivers, is suspicious, because impurities generally flow into them. Water which may have become polluted in any way by the excrements of cholera patients is especially dangerous. Special care must be taken that water that has been used in cleaning vessels or dirty linen does not get into or near wells or standing and running waters. The best protection against the pollution of well-water is afforded by iron tube wells driven straight and sufficiently deep into the earth (Abyssinian wells). 7. If it is impossible to get water that is free from suspicion, it must be boiled, and only boiled water used. 8. All this applies not to drinking-water alone, but also to all water used for domestic purposes, because germs of disease can be communicated to the body by water used in cleansing kitchen utensils, cleansing and cooking food, washing, bathing, etc. In general, the belief that drinking-water alone is to be regarded as the bearer of the virus, and that one is completely protected if only unexceptionable water is drunk, is urgently to be warned against. 9. Every cholera patient may become the starting-point for the further spread of the disease, and it is therefore advisable to send such patients to hospitals. If this is impossible, nobody must be permitted to approach them without necessity. 10. Never enter a house with cholera in it, except at the call of duty. Never visit places where many people are assembled in cholera times. 11. Never eat, drink, or smoke in rooms in which there are cholera patients. 12. As the evacuations of cholera patients are specially dangerous, clothes and linen soiled with them must either be burned at once or disinfected in the manner stated in the instructions for disinfection published simultaneously with this. 13. The most scrupulous care must be taken that cholera evacuations do not get near wells or rivers serving as sources of water-supply. 14. All articles which have come into contact with patients, and which cannot be destroyed or disinfected, must be rendered harmless by means of hot steam in special disinfecting establishments, or not used for at least six days, during which they are kept in a dry and airy place exposed as much as possible to the sun. 15. Persons who come into contact with a cholera patient or with his bedding or clothing should wash their hands at once. Do not touch food with unwashed hands or put into the mouth eating and drinking utensils, cigars, or anything else that may have been soiled in the sick room. 16. In case of death the corpse must be removed to a mortuary as soon as possible. If it cannot be washed there, it ought not to be washed at all. The funeral should be as simple as possible. The guests should not enter the house of death or take part in any funeral feast. 17. Articles of dress, linen, and other things that have been used by cholera patients or have been in contact with the corpses of such patients, must on no account be used or given to others till they are disinfected. Especially they must not be sent to other places unless disinfected. The receivers of packages, containing such articles, from cholera places are urgently advised to send them at once, if possible, to a disinfecting establishment, or to disinfect them themselves with the necessary precautions. Cholera linen ought not to be received for cleaning till it has been disinfected. 18. No other preservatives against cholera are known, and the public are advised not to use the so-called cholera-brandy and other alleged preservatives which are always extensively advertised in cholera times."

Dr. William F. Duncan, of Williamsbridge, N. Y., died at his home, on August 29th, of peritonitis.

Dr. Koch is reported to have said that the epidemic of cholera in Hamburg would die out as quickly as it had increased. If this report is true, it implies a confidence on his part in the efficacy of sanitary measures of Hamburg which has not been shared in the last two weeks by the world at large.

A Boom in Lysol.—The chief Sanitary Board of Austria has published, apropos of cholera, a statment regarding the value of some new disinfectants, in which it draws special attention to lysol. It says that the drug is speedily destructive to the comma bacillus, but is much less poisonous to man than is carbolic acid. A further advantage which lysol possesses over carbolic acid as a disinfectant of the hands, linen, etc., is that a solution of it renders the skin smooth instead of rough.

Sir Joseph Lister, having reached the age limit, will be retired from the teaching staff of King's College next year.

The Social Evil in New Orleans.—The City Council of New Orleans is considering the expediency of passing an ordinance requiring the registration and weekly examination of prostitutes.

Cheese.—The Treasury Department has forbidden the importation of rags, licorice-root, etc., from Europe and the East, on account of the danger of importing cholera germs at the same time. It would be well to keep out cheese also, since the comma bacillus is said to grow readily in this article of food.

Dr. W. Thornton Parker is to deliver a course of lectures on Medical Jurisprudence during the Session of 1892–3, at the College of Physicians and Surgeons, Chicago.

Yellow Fever.—The epidemic of yellow fever in Santos and other of the coast towns of Brazil, which has been raging with unparalleled intensity for upward of a year, is said to be abating. This is probably due to the fact that there is no more fuel for the disease to feed upon, and can in no sense be attributed to the action of the sanitary authorities, either national or municipal. Brazil has been disgraced among the nations of the earth by the supineness of her rulers in the face of such an epidemic.

The Carriers of Contagion.—About one hundred thousand Polish and Russian immigrants have come to this country in the past year, bringing with them the germs of typhus fever and small-pox. They have carried the cholera to the northern seaboard cities of Europe in most direct connection with this country, they have brought it already to our own shores, and doubtless many more are on the way with it.

Spanish-American Congress of the Medical Sciences.—This Congress will be held in Madrid in October next, in connection with the festivities commemorative of the discovery of America. A number of subjects relating to the influence of the discovery of America upon medicine, to acclimatization of men and animals, and to the peculiarities of practice in tropical America, will be discussed.

Dr. Henry S. Stark's Address is 270 Seventh Street. The address, 201 West Fifty-fourth Street, which appeared at the end of Dr. Stark's article in our issue of August 20th, should have been placed after the preceding paper by Dr. Peterson.

Wernicke's Atlas of Cerebral Anatomy.—The Berlin Academy has voted the sum of $200 to Professor Wernicke, of Breslau, toward the expense of the revision of his Atlas of Cerebral Anatomy.

Succi Fasting Again.—Signor Succi, who at last accounts had been declared insane, is now in Naples and has commenced a new fast there. A committee has been formed to watch him and observe the phenomena of circulation, respiration, weight, etc., and a bulletin will be issued daily.

Scarlet Fever is still epidemic in London, and complaint is made that the hospital accommodation is inadequate.

Licorice Root from Batoum is one of the articles to which entry has been refused by the Collector of Customs at New York. Batoum is in the infected region in Russia, and it is feared the bagging in which the licorice root is packed might convey the contagion of cholera.

Proposed Law Regarding Medical Expert Testimony.—The Minnesota State Medical Society has had the following bill drafted :

SECTION 1. In all cases pending in the courts of this State, civil and criminal, before or at the time of the trial of said cases, the Judge of said court, when it is made to appear to him that the appointment of experts upon medical, scientific, or mechanical questions is desirable, may appoint such experts to examine into the subject matter in controversy, said experts so appointed to be selected in reference to their impartiality between the contending parties; the number of such experts in each case to be fixed by the Court.

Sec. 2. In all cases where experts are so appointed, the Court is to fix their compensation, and in all criminal cases direct the payment of the same in the same manner as witnesses on the part of the State are paid; in all civil cases the amount so fixed and determined by the Court shall be taxed as disbursements by the successful party.

Sec. 3. The Court may order such experts to examine into any medical, scientific, or mechanical question, and after such examination to testify in court in reference thereto.

Sec. 4. The testimony of said experts so appointed by the Court shall be *prima facie* evidence of the statements and conclusions as to the questions in reference to which said testimony has been given.

Sec. 5. The Court may also fix and determine the amount to be allowed such experts for and on account of any medical, scientific, or mechanical examination, analysis or test, which the Court may deem advisable to have made, and direct the payment thereof, or permit the taxation thereof, as costs, as hereinbefore provided."

The Second Congress of Cuban Physicians will be held in Havana, in October of the present year. The Congress is held every second year, and should have met in January last, but it was decided to postpone it until October, in honor of the discovery of America. The following subjects have been proposed by the Committee on Organization for discussion: 1, Topography and statistics of any part of the island concerning which no description has yet been published; 2, Etiology of yellow fever; 3, Pro

phylaxis and treatment of yellow fever; 4, Clinical symptoms of yellow fever; 5, Pathological anatomy of yellow fever; 6, Etiology of tetanus; 7, Pathology of the liver in hot climates; 8, Paludism in its relation to pregnancy, child-birth, and the puerperal period; 9, Anatomy and physiology of the floor of the pelvis in women; 10, Has the knowledge of the pathogeny of diphtheria had any influence upon the results of treatment? 11, Comparative statistics of antiseptic therapy in Havana; 12, Reciprocal relations in their course of infections acquired simultaneously; 13, Is paludism the cause of the pernicious nature of the fevers in Havana? 14, Project of sanitation for the city of Havana; 15, Hygiene of private schools; 16, Investigation of alkaloids in cases of poisoning; 17, Experimental and clinical study of chronic diarrhœa; 18, The most common forms of skin disease in Cuba; 19, The abuse of alcoholic beverages in Cuba, its causes and most common pathological manifestations; 20, Affections of the lachrymal ducts; 21, Mutual benefit societies in their relations to physicians; 22, The visceral manifestations of gout in Cuba. The Committee has proposed a series of most interesting questions, and the intelligent discussion of them by the physicians of Cuba ought to be of immense service in widening our knowledge of diseases peculiar to tropical regions.

Strychnine in Cholera.—Dr. T. Ffrench-Mullen, of Bikamir, writes to the *Indian Medical Gazette* that he has used hypodermic injections of strychnine in some hundreds of cases of cholera within the last four months, and with very satisfactory results. He used the drug in every case where collapse seemed approaching or had set in, the dose being five minims of liquor strychninæ in an equal quantity of water. As his cases were almost all seen in their houses, and there were so many to be visited, it was, as a rule, only possible to give two injections in the day to any one case, that is, when on the morning and evening rounds. He gave, however, five injections in the twenty-four hours, and two more during the following twelve hours, in the case of a prisoner where the effects could be watched, and has no doubt the man owed his recovery to this remedy. When the urinary secretion had not been re-established within twelve hours or so of the cessation of the other symptoms, he used hypodermic injections of pilocarpine with, in many cases, marked success, the urine being passed within less than five minutes after the use of the syringe.

Quarantine Regulations.—Dr. Jenkins, Health Officer of the Port of New York, has issued the following order to the representatives in this city of the different steamship lines:

"All vessels from cholera-infected ports, or carrying steerage passengers from infected localities, will be subjected to quarantine of detention from two to five days. Passengers and their baggage will be transferred to Hoffman Island, where they will receive a bath, while baggage and clothing are disinfected by steam. Immediately after such transfer steerage and cargo will be disinfected. The passengers will be then returned to the vessel, which in absence of any development of suspicious cases will be allowed to proceed to her dock. This regulation is in accordance with a telegram sent to the Secretary of the Treasury, requesting that the same regulations at the port of departure be enforced under the direction of the United States Consul. If the Health Officer is satisfied upon investigation that such regulations have been carried out at such ports, in regard to emigrants, the above regulations will be modified."

Dr. Obermueller, physician to the Czar, died in St. Petersburg on August 27th at the age of fifty-five years. His death is said to have been caused by cholera.

Circular of the Board of Health Relating to Cholera.—The following are the instructions to be issued by the New York Board of Health in case of the appearance of cholera in this city. They will be printed in English, German, Italian, French, and Hebrew:

"Healthy persons 'catch' cholera by taking into their systems through the mouth, as in their food or drink, or from their hands, knives, forks, plates, tumblers, clothing, etc., the germs of the disease, which are always present in the discharges from the stomach and bowels of those sick with cholera. Thorough cooking destroys the cholera germs; therefore: Don't eat raw, uncooked articles of any kind, not even milk. Don't eat or drink to excess. Use plain, wholesome, digestible food, as indigestion and diarrhœa favor an attack of cholera. Don't drink unboiled water. Don't eat or drink articles unless they have been thoroughly and recently cooked or boiled, and the more recent and hotter they are the safer. Don't employ utensils in eating or drinking unless they have been recently put in boiling water; the more recent the safer. Don't eat or handle food or drink with unwashed hands, or receive it from the unwashed hands of others. Don't use the hands for any purpose when soiled with cholera discharges; thoroughly cleanse them at once. Personal cleanliness and cleanliness of the living and sleeping rooms and their contents, and thorough ventilation, should be rigidly enforced. Foul water-closets, sinks, Croton faucets, cellars, etc., should be avoided, and when present should be referred to the Health Board at once, and remedied.

"The successful treatment and the prevention of the spread of this disease demand that its earliest manifestations be promptly recognized and treated; therefore: Don't doctor yourself for bowel complaint, but go to bed and send for the nearest physician at once. Send for your family physician; send to a dispensary or hospital; send to the Health Department; send to the nearest police station for medical aid. Don't wait, but send at once. If taken ill in the street, seek the nearest drug store, dispensary, hospital, or police station, and demand prompt medical attention. Don't permit vomit or diarrhœal discharges to come in contact with food, drink, or clothing. These discharges should be received in proper vessels and kept covered until removed under competent directions. Pour boiling water on them, put a strong solution of carbolic acid in them (not less than one part of acid to twenty of hot soap-suds or water). Don't wear, handle, or use any articles of clothing or furniture that are soiled with cholera discharges. Pour boiling water on them or put them into it, and scrub them with the carbolic acid solution mentioned above, and promptly request the Health Board to remove them. Don't be frightened, but do be cautious, and avoid excesses and unnecessary exposures of every kind."

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, held at Nottingham, July 26, 27, 28, and 29, 1892.

SECTION ON OBSTETRIC MEDICINE.

FIRST DAY, WEDNESDAY, JULY 27TH.

President's Address.—DR. GALABIN, the Chairman of the Section, in his opening address drew attention to the way in which surgery now predominated in the treatment of diseases of women. In reviewing the improvements which had taken place in obstetrics, he said that extra-uterine gestation had been shown to be a much more frequent affection than previously supposed. The occurrence of tubal abortion was still a matter of controversy. He was convinced that a clot might be formed in a Fallopian tube with open extremities, without the occurrence of fœtation.

Many of the cases which were formerly called abdominal gestation were intra-ligamentous, which was a better name than subperitoneal; or they might be called mesometric, the ovum getting in by separation of the mesosalpynx, and some sort of pedicle could generally be made out which could be ligatured. In some cases of intra-ligamentous pregnancy the tube dilated to a considerable extent, and he cited a case in which it had so dilated as to contain thirty-six ounces of pus without rupture occurring.

With reference to the application of abdominal section to the treatment of placenta prævia, he thought that the older methods gave better results than were likely to be obtained by it, but it might be useful in some cases of accidental hemorrhage.

Abdominal section for puerperal peritonitis had not been very successful, except when the tubes were the source of the mischief, as even if the whole uterus were removed, as had been advocated, there was a probability that there would be other septic foci left behind.

The treatment of post-partum hemorrhage had been improved by the introduction of the methods of injecting hot water and plugging the uterus, and the treatment of the anæmia resulting by the injection of large quantities of normal saline solution, which was useful providing the bleeding had been stopped.

Post-partum Hemorrhage.—DR. HERMAN, of London, in opening a discussion on this subject, said that bleeding in all parts of the body was stopped by pressure, and in the treatment of post-partum hemorrhage no method could be relied upon which did not act by causing compression of the vessels. The surest way of causing post-partum hemorrhage was to drag out the child before the uterus was ready to contract. There was no necessity to hasten delivery when the uterus was quiescent, as no pressure effects would be caused by that condition, which was the opposite of the state of tetanic spasm set up by long-continued efforts of the uterus to overcome an obstruction. The right line of treatment in ante-partum hemorrhage was to get contractions to occur before delivery was brought on It was very important always to see that the whole of the chorion was removed.

The methods of arresting post-partum hemorrhage might be divided into three groups: A contraction was encouraged by, 1, direct stimulation; 2, reflex stimulation; and 3, drugs. Under the first head were mentioned kneading with the hand outside of the abdomen, the hand in the uterus, hot water, and electricity. Reflex stimulation could be obtained by means of cold cloths applied to the vulva and abdomen, and by putting the child to the breast. The only drug in which the speaker had any faith was ergot. He did not approve of the use of perchloride of iron as a styptic.

As regarded plugging the uterus with gauze, there was some danger. One case of death from entrance of air into the veins had been reported.

The treatment was unphysiological, for when the uterus would contract by the gauze, it might be made to contract by other means.

In summing up, the author held that the best means of stopping post-partum hemorrhage was by continued compression, and the best means of doing this was with one hand on the abdomen and the other with its fingers flexed passed into the vagina, the fundus being compressed between the two.

DR. MORE MADDEN, of Dublin, said that the most frequent cause of fatal hemorrhage was the hemorrhagic diathesis, and this was more frequent among the poor in Ireland than in England. He advocated tablespoonful doses of ergot before the birth of the child, in cases in which post-partum hemorrhage was anticipated.

DR. BYERS, of Belfast, in discussing the question whether chloroform promotes post-partum hemorrhage, took the side that it did not promote hemorrhage.

DR. HORROCKS, in continuing the discussion, said the uterus was sometimes relaxed without hemorrhage occurring. Throughout pregnancy it alternately contracted and relaxed, and the same occurred post partum. He did not think that chloroform promoted hemorrhage.

DR. H. R. SPENCER, of London, drew attention to frequency of lacerations as a cause of post-partum hemorrhage; in these plugging was an excellent treatment. He had treated eight cases of severe anæmia, likely to prove fatal after hemorrhage, by the intra venous injection of normal saline solutions, with four recoveries.

DR. PURSLOW, of Birmingham, thought many cases were due to the abuse of Crédé's method of expelling the placenta, forcible expression being used too soon after the birth of the child. The speaker had always found cases yield to pressure of the uterus and injection of hot water, and had never used iron.

DR. MURDOCH CAMERON, of Glasgow, thought that an important point in the preventive treatment was the early use of forceps. Many cases resulted from leaving the membranes in utero. He did not use ergot and never used perchloride of iron, but believed in kneading the uterus.

DR. WALTER, of Manchester, related a case in which plugging the uterus was tried; the uterus dilated further above the plug, and hemorrhage had subsequently to be arrested by hot water.

DR. ROBERT BARNES, of London, remarked that there would be cases of post-partum hemorrhage in spite of all preventive means. He always used hot water first and believed very strongly in it, but it was no good when there was no reflex response to irritation, and in those cases we must use perchloride of iron. He did not believe in ergot before the birth of the child. He had found hot water injection better than cold; he had tried the alternate injection of hot and cold, but had given it up.

MR. STANMORE BISHOP, of Manchester, advocated compression of the abdominal aorta.

DR. PARKINSON thought a preliminary course of tonic treatment was a good preventative.

DR. CULLINGWORTH, of London, would emphasize the order of treatment laid down by Dr. Herman, to wit: 1st, external manipulation; 2d, combined external and internal manipulation; 3d, injection of hot water. He did not believe that iron or plugging were ever needed after proceeding as above.

DR. GALABIN thought it difficult to compress the uterus when it was completely relaxed. He would plug the uterus with iodoform gauze in preference to using perchloride of iron injection. He thought the plug acted in a reflex manner by setting up contraction, and not by direct pressure, and doubted if anything would save the patient when contraction could not be obtained.

Prevention of Hemorrhage in Cæsarean Section.—DR. MURDOCH CAMERON discussed this question. He said the elastic band induced inertia and might lead to

hemorrhage later. He had used a flat Hodge pessary pressed on the uterus by an assistant, the incision being made through the centre of the pessary. He would never extract the placenta before the child, as contractions might be set up and reuder delivery of the child difficult. The uterus should not be everted until after the birth of the child. It was quite unnecessary to avoid the middle line of the uterus, even if the placenta were situated there. An assistant should grasp the edges of the uterine wound and press them together. A flat warm sponge should be pressed on the uterus, and this never failed to cause contraction. He would advise never to pack the uterus or to wash it out.

Dr. Heywood Smith, of London, mentioned a case in which after Cæsarean section the uterus would not contract; he passed in a lump of ice and this had the desired effect.

Dr. H. R. Spencer had found the pessary, as advised by Dr. Cameron, fail in a case in which fibroids were present.

Septic Hydræmia Following Miscarriage.—Dr. J. Headley Neale, of Leicester, reported the case of a "Septic Hydræmia Following Miscarriage." The woman, thirty-five years old, who was admitted to hospital with intense œdema of the whole body, had miscarried six weeks previously, and the swelling had come on since. There was no albuminuria and no cardiac murmur. She was tapped in the legs on several occasions, and three and a half gallons of fluid drawn off. She died suddenly on the tenth day. On post-mortem examination fluid was found in the serous cavities; the uterus was œdematous and contained a small piece of retained placenta. The speaker thought the symptoms were due to septic poisoning from the retained fragment.

Second Day, Thursday, July 28th.

Radical Cure of Retroflexion.—Dr. Braithwaite, of Leeds, read a paper on this subject.

He separated the bladder from the uterus, after incising the anterior fornix, without opening the peritoneum. The anterior surface of the uterus being brought into view, a strong silk ligature on a specially curved needle was passed through the supra-vaginal portion of the cervix, then through the fundus, and back through the cervix, and tied, being then completely buried. The cervix had been previously dilated so as to allow the introduction of the finger, by means of which the uterus was placed in position before passing the ligature. This operation was only advisable in very severe cases.

Dr. Heywood Smith advocated ventral fixation, and thought that in some cases this might be done without an abdominal incision.

Dr. Leith Napier, of London, condemned the attempt to pass sutures in ventral fixation without opening the abdomen. He thought ventral fixation by abdominal section was preferable to a vaginal operation, and easier.

Dr. Batchelor said that in cases where there were no adhesions, he preferred Alexander's operation. Where there was fixation, abdominal section was better, as it allowed an opportunity of examining the parts.

Dr. Galabin doubted whether the silk loop would not set up suppuration. He was not fond of abdominal fixation, and in cases free from adhesions he found pessaries to answer the purpose.

Twin Tubal Pregnancy.—Dr. Walter, of Manchester, reported a case of tubal gestation in which both tubes were gravid. The patient had had six children, the last four years ago, and was admitted with pain in the abdomen, difficulty in micturition and defecation. The periods had been too frequent, the last one was at the end of July, 1891, after nine weeks' amenorrhœa, with symptoms of pregnancy.

On the left of, and close to, the uterus, there was a tender mass the size of an orange. The patient was allowed to go home and was seen again in December; the swelling was then the size of a hen's egg. She was admitted again February, 1892, and operated on. She had missed the last period, and on the day before the operation had an attack of pain and diarrhœa.

At the operation clotted blood was found in the peritoneal cavity; there was a swelling on each side of the uterus. The tubes were removed and sent to Mr. Bland Sutton, who reported as follows:

"Specimen consists of two Fallopian tubes, the left one the larger, and occupied by an apoplectic ovum with an embryo in the amniotic cavity.

"Right tube, abdominal ostium closed. Interior contains a tubal mole, amniotic cavity, but no fœtus. Microscopic section showed chorionic villi."

This was the first reported case in which undoubted tubal pregnancy on both sides occurred; some cases had been reported as such, but the existence of pregnancy had not been indubitably proved.

Dilator of Champetier de Ribes.—Dr. Herman described this cervical dilator, which was a large balloon-shaped bag made of silk, which was introduced through the cervix by grasping it in a special pair of forceps, and when in the uterus, distended by injecting water into it. It would hold seventeen ounces of fluid, and as it was inelastic, could not be poured out until the cervix was thoroughly dilated.

Its advantages over Barnes's bags were, that several operations for introducing sizes were not necessary, and that it was not possible with Barnes's bags to get complete dilatation.

In four cases the time required to produce dilatation by this bag had been from six to twenty-four hours. The speaker had tested the compressibility of the bag, and found that its diameter, which was three and one-half inches when distended, could only be reduced by pressure to three inches.

Dr. Robert Barnes, of London, pointed out that Champetier's bag displaced the fœtal head, and thought that the sudden distention of the lower uterine segment which was caused might produce rupture. The first idea for his own bags, which he brought out in 1869, was like that of Champetier, but he gave this up for the well-known fiddle-shaped ones.

Dr. Murphy, of Sunderland, praised Barnes's bags and thought that bursting, when produced, was always the result of not observing carefully the amount of water injected.

Dr. Spencer, of London, had found Barnes's bags slip out, and had seen the larger sizes produce œdema of the vulva and vagina; he thought Champetier's bag would be the method of the future for the induction of premature labor.

Stoltz's Operation for Cystocele.—Dr. Leith Napier, of London, then read a paper with this title. Cystocele was a hernia of the bladder through the muscular fibres of the vaginal wall. An ordinary cystocele, or what he preferred to call colpo-cystocele, was generally associated with prolapse of the uterus; the most important cause of this was parturition. For prolapse of the anterior vaginal wall, Stoltz's method was the only satisfactory one.

He first made a circular denudation of the wall, and then passed a silk thread from the upper end with a needle at each end, so as to form a circular buried purse-string suture. The centre of denudation was then pushed up while the knot was tied. The ligature was passed before denuding the surface, and removed in ten days by cutting the knot.

Dr. Heywood Smith had performed the operation, and thought passing the ligature before denuding the surface puckered up the mucous membrane and made denudation more difficult.

Third Day, Friday, July 29th.

Treatment of Fibroids of the Uterus.—Mr. Knowsley Thornton, of London, in opening the discussion on this subject, said that there were many cases where no symp-

toms were present, and the tumor was only found accidentally; in those cases he thought it better not to inform the patient of the existence of the tumor. There were other cases in which medical treatment would do all that was necessary. This consisted in regulating the diet, forbidding stimulants, and giving ergot during the intervals between the periods; this treatment in many cases sufficed to stop the hemorrhage. He would never administer iron, and though other drugs had been tried, he considered ergot by far the best. When there was pain during a period from the retention of menstrual blood, the passage of a No. 8 or 9 bougie just before the period often gave relief. The curette might be used with advantage to check hemorrhage. In the case of growths which rose above the pubes, an abdominal belt, by supporting the tumor and preventing its movement, often gave great relief. In most cases both large and small fibroids were found to disappear after the menopause. Although relief was sometimes given, he had never known a single case cured by baths or mineral waters. Of electricity, he had no personal experience, but he was not satisfied that any single case was ever cured by it; in some cases it might check hemorrhage, but so would some other intra-uterine applications. It might cause temporary shrinkage of the tumors, to be followed by increased rapidity of growth. He had operated on cases in which the electrical treatment had previously been tried, and bad results had followed. His own experience of vaginal enucleation had been singularly unfortunate; he thought it a much more dangerous operation than abdominal section, and one could not be sure that there were not other tumors remaining after the operation.

The speaker would avoid enucleation as much as possible, and where it was unavoidable would use the strictest antiseptic precautions. He thought that for dilating the cervix, tents, when thoroughly antiseptic, were the best means, but as their asepsis could never be depended on he preferred to use rapid dilatation by bougies. He thought that the internal os was always lacerated when the cervix was sufficiently dilated to allow of enucleation. In the after-treatment of enucleation he would plug the vagina with iodoform gauze and leave the plug in for several days. He would keep the patient in bed for ten days, and after removing the plug would douche the vagina frequently. If much subsequent oozing occurred he would apply perchloride of iron and plug the uterus. Coming to the relative value of oöphorectomy and hysterectomy, he said that he would never decide on which operation to perform until the abdomen was opened and the parts examined. He believed that removal of the ovaries was a certain cure when all ovarian tissue was removed, though the result was in some cases rapid and in others slow. The mortality of the operation in his own hands had been about four per cent., and he believed death had been due in most of these cases to the puncture of large vessels by the needle. He thought it well always to transfix the ovarian ligament. He kept the patient in bed for three weeks after the operation. The best time to choose for the operation was shortly before the period was due, the reasons being that the patient was then in her best condition, having recovered from the loss of the last period, and that all being now ready for the next period, all that the operation did was to hasten it. With reference to hysterectomy, he thought that the supra-vaginal operation with extra-peritoneal treatment of the stump was the best operation. The ovaries might be removed or left, but he thought it advisable generally to leave them.

Dr. James Murphy, of Sunderland, advocated treatment by morcellement, that is, tearing away the tumor piecemeal with suitable forceps, after dividing the capsule. He narrated a case in which there was a large tumor in the posterior wall with the uterus retroverted, which he had treated in this way with success.

Dr. Horrocks, of London, thought there were different kinds of fibroids, but clinically these tumors were not malignant and seldom caused death. He had never seen a death from hemorrhage, and would not, except in a few cases, recommend surgical treatment.

The age of the patient was important in deciding upon the line of treatment. He had never seen a tumor disappear, though they sometimes diminished in size. He thought electricity did good, but had been compelled to stop the treatment on account of pain. The current really acted as a caustic. He thought that all were agreed that the positive pole was a hæmostatic.

Dr. Leith Napier, of London, thought that when a fibroid began to grow after the menopause, it was much more serious and required surgical treatment. He had seen cases of very severe and prolonged hemorrhage eventually recover spontaneously. He did not see any good in leaving the ovaries in hysterectomy. It was sometimes impossible to find the ovaries, and he would then tie tubes and remove them. He advised tying the uterine arteries first to arrest hemorrhage from the stump.

Dr. Tivy, of Bristol, had used the electrical treatment for five years and had seen no bad results. He used a current up to 150 milliampères.

Mr. Lawson Tait, of Birmingham, did not consider it necessary to remove the ovaries completely, and often left part of one in performing oöphorectomy for fibroid. He had found the mortality of hysterectomy increased from seven or eight per cent. to fifty per cent. in cases in which the electrical treatment had been previously applied. He thought that electricity might sometimes temporarily stop hemorrhage, just as the application of iron or alum would.

Dr. Elder, of Nottingham, said that he had at first used electricity, but had found that the results were not permanent, and had even seen sloughing follow its use.

Dr. Michie, of Nottingham, thought there was a nerve-centre for the function of menstruation, and that its arrest depended on the severance of the nerve-connection.

Mr. Stanmore Bishop, of Manchester, advocated the intra-peritoneal treatment of the stump in hysterectomy, and thought the greatest danger was of septic infection from the mucous membrane of the cervical canal.

Dr. Murdoch Cameron, of Glasgow, said he had seen these tumors disappear when treated by electrolysis.

Dr. Heywood Smith, of London, would operate in cases where there was pain, rapid growth, and hemorrhage. Operation is sometimes unavoidable, especially in the lower classes.

Dr. Batchelor thought Dr. Horrocks had much underestimated the death-rate from fibroids, and had not taken into account many other causes of death besides hemorrhage.

Dr. Spencer would like to ask Mr. Thornton what he would do with a large intra uterine tumor which was gangrenous and being delivered, and whether he thought removal of the ovaries was successful in cases of soft myoma.

Dr. Cullingworth, of London, would ask Mr Thornton why he insisted on giving ergot during the menstrual interval only? He would leave one or both ovaries in hysterectomy.

Dr. McVittie, of Dublin, thought the intra-polar action of electricity was much more important than the local action. He would use large cells and a low tension current.

Mr. Thornton, in reply, said all were agreed that fibroids should not be interfered with surgically except in extreme cases. But he drew attention to the living death which many patients with fibroids suffered, and he would in those cases operate. He had never seen a case of insanity follow operation for fibroid tumor. He believed that many women suffered real misery from the artificial menopause brought on by operation. He had in one case completely removed the tubes and left the ovaries, and menstruation had gone on; he thought it could not depend on the tube alone.

In reply to Dr. Spencer's question, he said he would enucleate the tumor.

Anatomy of the Hymen.—Dr. Cullingworth, of London, read a paper entitled "Some Remarks on the Anatomy of the Hymen and of the Posterior Commissure of the Vulva." The hymen was, he said, generally described as circular or oval, and its edges apart. This could only be true when the labia were forcibly separated. In the adult virgin it was normally concealed by the labia minora with their internal surfaces in apposition. On separating these the edges of the hymen were seen lying in apposition; no actual opening was seen, but simply a vertical slit. The free borders of the hymen were straight or denticulate, and their upper extremities met in front in a fold which partially enclosed the urethral orifice, and formed the elevation which marked the opening of the urethra; this fold disappeared when the hymen had been stretched. He had never seen a case in which the hymen could not be found. He had never seen a cribriform hymen, and thought its existence problematical. A fold analogous to the hymen had been demonstrated by Mr. Shattock at the orifice of the prostatic vesicle in man. The posterior commissure had been shown to be the posterior junction of the labia minora, as in cases in which these were deeply pigmented a line of pigment could be traced uniting them posteriorly. The fossa navicularis was situated between the fourchette and the posterior part of the hymen.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 24, 1892.

H. P. Loomis, M.D., President in the Chair.

Musical Heart Murmurs, and the Chordæ Tendinæ.—Dr. H. S Stearns said that, a little less than three years ago, Dr. E. Hodenpyl had presented to the Society several specimens showing the chordæ tendinæ stretched across the left ventricle, and the question has been raised whether they gave rise to any abnormal sound. The specimen which he was about to present showed a similar condition. The specimen had been removed from a man who during life had had a musical systolic murmur at the base of the heart, and transmitted to the vessels of the neck, and also a diastolic murmur at the base, not transmitted into the vessels of the neck.

Dr J. M. Byron said that the specimen was not only very interesting, but quite rare. He had seen two similar cases in which the condition had been diagnosticated during life by the musical sound produced during the systole of the heart. In the specimen presented, the inferior chorda tendina could not have produced the musical murmur, for the heart would have emptied itself before this band would have enough tension to give rise to a musical vibration. The sound may have been produced by the band across the upper part.

The President said that he had followed the case at the bedside very closely. The murmur was peculiarly loud and blowing, and was heard all over the præcordial space. It had been supposed to be due to the flapping of an eroded valve. At the time of his admission, the symptoms were those of advanced heart disease. He agreed with the preceding, that the sound was produced by the upper chorda tendina.

Dr. J. S. Ely said that, by way of corroboration of what had been said, he would remind the Society that in Dr. Hodenpyl's specimens the chordæ tendinæ were stretched across the lower or apical portion of the heart, and that in his cases there was no musical murmur.

Thrombosis of the Middle Cerebral Artery.—Dr. Stearns also presented this specimen. It had been removed from a man forty-five years of age, who had been brought to the hospital in an ambulance in a stupid condition, with a temperature of 104° F., suffering from intense headache, and unable to speak distinctly. According to his friends, he had been sick for about two weeks, the stupor gradually deepening. After his admission, it was thought possible that he had typhus fever, and he was accordingly isolated. Under moderate doses of quinine the temperature fell to 101° F., and he continued in this same dull condition with all of the general symptoms of pachymeningitis, with the speech symptoms particularly prominent. About four days before his death, he got out of bed, and while walking across the ward, fell in a faint. After this he was found to have motor paralysis on the right side, sensation was diminished, and was associated with formication. He remained unconscious from this time until his death. The case was seen by a number of physicians, and a diagnosis was made of pachymeningitis with a possibility of a cortical hemorrhage. At the autopsy the aorta was found moderately atheromatous, the heart was normal, and the left middle cerebral artery contained a thrombus nearly one inch in length and apparently completely occluding the vessel. Nothing was found in the interior of the brain, but in the island of Reil there was a patch of white softening about four-fifths of an inch in diameter. This may not have extended sufficiently deep to account for the motor symptoms, but it was certainly in just the position to explain all the speech symptoms.

Polypoid Spindle-celled Sarcoma of the Uterus.—Dr. George C. Freeborn presented a specimen of the above. It was removed from a woman fifty-one years of age, who was married, but had never had any children. Twelve years ago one of her breasts was removed for cancer, a secondary operation being performed in 1889. The exact nature of this supposed cancer could not be ascertained. The specimen in the fresh state was of an irregular pear shape, and measured 5½ ctm. in length and 3 ctm. in its widest part. On longitudinal section, the mass was found to be composed of a central portion, mottled white and red, and of a fairly firm consistency, enclosed in a capsule which had an average thickness of two millimetres. Microscopical examination of this central mass showed it to be made up of moderately large, irregular spindle-cells, embedded in a loose connective-tissue stroma, and a large number of thin-walled blood-vessels. The capsule was found to be the uterine mucous membrane in a state of chronic endometritis. The pedicle of the tumor was a mass of sarcoma.

Cyst of the Ovary and of the Fimbriæ of the Tube.—Dr. Freeborn also presented specimens of the above. They were removed from a woman forty-four years of age, married, and having one child. She first noticed a "lump" in the lower part of the abdomen two years ago, and this had steadily increased in size up to the time of the laparotomy. The first specimen, the right ovary, showed a cyst 18 × 17 ctm. in circumference, which was filled, in the fresh state, with a clear mucilaginous fluid. The Fallopian tube with its fimbriated extremity were firmly attached to the cyst wall, and both tube and cyst were covered with thin adhesions. A small ovoid cyst projected from the posterior surface of the first cyst. Microscopical examination showed the cyst wall to be composed of fibrous tissue, without any trace of ovarian tissue except at a point just anterior to the tube, where there is a corpus luteum.

The second specimen showed, in the fresh condition, the ovary to be an irregular triangular-shaped mass, 27 × 23 × 13 mm, with its surface deeply corrugated and covered with thin adhesions. The outer two thirds of the Fallopian tube was converted into a thin-walled cyst, filled with a clear fluid. On section, this cyst of the tube was found to be composed of a series of small cysts. Microscopical examination showed the inner third of the tube in a state of advanced catarrhal salpingitis, and the walls of the cysts made up of fibrous tissue lined with cuboidal epithelium.

An Improved Method of Staining.—Dr. J. M. Byron said that in examining bacteria in tissues and in many fluids, the following method of staining would be found less difficult and more reliable than those usually employed: For cover-glass preparations, such as sputum, pus, blood, etc., the cover-glasses are smeared with the

fluid in the usual way, and then directly plunged without drying into a solution consisting of one part each of eosin and bichloride of mercury, and alcohol one hundred parts. They remain in this fluid for about one minute, and are then washed and plunged into a dilute aniline water, *e.g.*, gentian-violet solution, for a minute or two; then in absolute alcohol, xylol, and finally mounted in balsam. Cover glass preparations of blood are beautifully stained in this way, the red corpuscles purplish-red, granules and plates red, and bacteria a deep blue.

Sections of tissues are first transferred from alcohol to the gentian-violet solution for a few minutes, then placed directly in the solution of eosin and bichloride in alcohol. This unstains everything except the bacteria, and the tissues take the eosin, while the nuclei are stained a light purple. Specimens of gonococci are remarkably well double-stained by this method.

Extreme Eccentric Cardiac Hypertrophy.—Dr. Warren Coleman presented the specimen. It was removed from a man sixty-one years of age, who up to two years ago had led an active business life. Since then he had been subject to attacks of vertigo, and had presented most of the symptoms of aortic stenosis and regurgitation, but the gravity of the condition was not appreciated. Only five years ago, he was admitted to a large insurance company. He was a large-built man and well nourished. On the night of his death, he got out of bed to get something out of his coat, when he dropped unconscious, and almost immediately died. A physician was hastily summoned, and he performed artificial respiration, as this had succeeded in a similar attack a few weeks before. Death probably resulted from over-distention of the heart.

At the autopsy, the pericardium was found very much distended and tightly stretched over the heart, the lungs being pushed backward and upward. The left ventricular wall was one and a half inch in thickness, and its cavity somewhat dilated; the heart weighed twenty-eight ounces. The aortic semilunar valves were the seat of a calcareous deposit, varying from one eighth to one-fourth of an inch in thickness. The valvular orifice was small. The aorta held water imperfectly. The mitral valve admitted three fingers with difficulty. The right heart was perfectly normal with the exception of being of a rather light color, probably due to fatty degeneration.

Epithelioma of the Right Labium.—Dr. Coleman also presented a specimen of the above, on account of the comparative rarity of epithelioma in this situation. It was removed from a woman thirty-six years of age, who gave a specific history. About one year ago, she noticed a small pimple on the right labium, which grew slowly until about three months before the operation, when its growth was more rapid. The whole labium was found to be infiltrated, and its inner surface very deeply ulcerated. The specimens which he had placed under the microscope exhibited only one or two epithelial pearls in a series of sections, and at first glance one would consider it a carcinoma, except for a certain regularity of the cells.

Dr. Coleman presented specimens showing "Chronic Cystitis, and Multiple Abscesses of the Kidneys." There was probably a cystitis followed by an inflammation of the kidneys, and the formation of abscesses.

Bronchial Casts in Fibrinous Bronchitis.—Dr. Coleman also presented gross and microscopical specimens of this condition. The patient from whom they were taken was a man sixty-six years of age, who had a good family history, and who had enjoyed excellent health up to the time of this present trouble. Every three or four days he is seized with severe paroxysms of coughing, which terminate after several hours by the ejection of these bronchial casts. In the intervals he did not suffer at all from dyspnœa. He had also an aortic systolic murmur, and some left cardiac hypertrophy, with feeble respiration over the left lung posteriorly, without any change in the percussion note. These bronchial casts are generally found in the young adult female of delicate constitution, and there is very commonly a history of hemorrhages, but this patient gave no such history. Microscopical examination showed a central canal, radiating from which were separate portions of tissue which seemed to be made up of more closely interwoven fibres. Some fibres ran longitudinally, and some transversely, and toward the outer portion there were concentric layers apparently indicating that coagulation had taken place gradually. A number of pus-cells were found in the meshes of fibrin.

Epithelioma of the Larynx.—Dr. Coleman also presented gross and microscopical specimens of epithelioma of the larynx. According to the history, the thyroid cartilage was involved in the disease, and was considerably ulcerated, and the whole larynx seemed to be filled with the neoplasm. The clinical history certainly pointed toward malignancy. There had been some difference of opinion among those who had examined the growth concerning its nature, some maintaining that it was a carcinoma, while others agreed with him in the diagnosis of epithelioma. Immediately after the removal of the specimen, it had been placed in ninety-five per cent. alcohol, and on this account it was greatly shrunken. Microscopical examinations had been made of the outer, inner, and middle portions of the growth.

Several members present examined the specimen under the microscope, and expressed the opinion that it was an epithelioma.

Anthracosis—Small Pleuritic Thickenings.—Dr. J. S. Ely presented the lungs from a case of lobar pneumonia. They were removed from a man about fifty years of age, who was brought by the ambulance to the Roosevelt Hospital in a condition of extreme collapse, and died almost immediately after admission. The autopsy showed the upper portion of the right lung completely consolidated and in the stage of gray hepatization. The visceral pleura was covered with a thin pellicle of new fibrin, besides some thickened fibrous bands from an old pleurisy. With the exception of these slight adhesions, there were none in either lung. A portion of the left lung was deeply pigmented, apparently from the inhalation of coal dust. In addition to this, in very many places over the surface of the lung there are small gray spots, one eighth of an inch or less in diameter, each one of which is surrounded by a small black zone. These spots are slightly irregular in outline, do not seem to be elevated, and are scattered about equally over the upper and lower lobes of both lungs. In the upper lobe of the left lung there are many grayish spots, which are apparently due merely to a fibrous thickening of the pleura. They might possibly be mistaken for miliary tubercles. A microscopical examination shows them to be small areas of fibrous thickening in the pleura, and not in the lung under the pleura. They were unusually abundant in this specimen. In many other specimens they seem to be situated at the points of junction of the lobules.

In 1885, Julius Arnold, of Heidelberg, in an essay on the inhalation of dust, considered the small lymphatic structures scattered through the lungs, more particularly at the angles formed by adjacent lobules, very potent factors in causing these deposits of pigment. The speaker had thought these fibrous thickenings of the pleura might be secondary to the deposits of anthracotic pigment, but he had been in some doubt about this since examining them microscopically, as these gray dots, although surrounded by pigment, apparently have none within them. The thickenings are probably the result of small areas of inflammation on the pleura, which by interference with the circulation, favor the subsequent deposition of the coal-dust.

The President said that he had never seen them except in lungs which were much pigmented. He suggested that they might be secondary to localized inflammations set up by irritating or infectious material brought to the surface of the lungs by the lymphatics.

Dr. Byron asked if these nodules were found to

correspond to any lymphatics or capillaries in the tissue. This was a very important point in pathology, and might furnish a clue to the pathogenesis of the lungs. It was not at all uncommon for these nodules to be mistaken for miliary tubercles. That they are not due to the pigment was shown by the fact that the nodules did not contain any pigment. He had made some experiments in connection with the subject under discussion, and he considered it worthy of close study and investigation. Tuberculosis, anthracosis, actinomycosis, leprosy of the lungs, he considered neoplastic infectious diseases, nearly always due to infection through the lymphatics, and that these nodules represented the first stage. He had found them not only on the surface of the pleura, but deep in the lungs.

Dr. ELY said that these were not simply lymph-nodules which had undergone interstitial change, for those in the immediate neighborhood remain unchanged. There were no tubercles in this patient.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BRITISH MEDICAL ASSOCIATION—THE HOLIDAY SEASON—THE LOCUM TENENS—MR. ALLINSON'S APPEAL—THE FULHAM SCARLET FEVER CASE AGAIN—THE MATTEI BUBBLE—THE LATE MR. SAMUEL ARMSTRONG LANE.

LONDON, August 13, 1892.

THE annual meeting of the British Medical Association may be said to virtually close the medical year. No professional gatherings of any note will now be held until the autumn, the medical schools are closed, and most practitioners are either thinking of—or are in actual enjoyment of—their annual holiday. No large assembly of members can, therefore, be expected at the extraordinary General Meeting of the British Medical Association, to be held on the 24th inst. The object of this special meeting is to consider, and if thought fit, to confirm, the resolution which was passed at Nottingham, rescinding the prohibition at present existing in the Articles of Association to the admission of duly qualified medical women to the society. The date of meeting is fixed in accordance with the by laws of the Association, which require a resolution of this kind to be confirmed at a general meeting held a few weeks later, and on the present occasion is a very unfortunate one. It is quite possible, under the circumstances, that the decision of the Nottingham meeting may be reversed, though there can be but little doubt of the ultimate issue now that the question has been raised. As one of the speakers at Nottingham put it, women are now admitted to the medical profession, *i.e.*, to a body which is greater than the British Medical Association; it was therefore unreasonable to refuse them admission to the lesser body. It is noteworthy that the extraordinary general meeting is announced to take place in London instead of in Birmingham, where several extraordinary meetings have been held in former years. The Association, however, is becoming more and more of a metropolitan institution, controlled largely by metropolitan influence. This is the more remarkable as it was founded originally as the Provincial Medical and Surgical Association, and the early members were almost exclusively drawn from provincial towns. At the Nottingham meeting the provincial members predominated, as was to be expected from the geographical position of the town, but about a hundred and fifty members came from London and the suburbs of London—a much larger number than at many annual meetings within recent years.

With the advent of the holiday season the question of what is to be done for patients during that time comes to the front. The practitioner wants his holiday, but patients cannot all be persuaded to get well by a certain date, as we have not yet learned the art of regulating illnesses by the almanac. It is at this season of the year that the locum tenens comes into special prominence and asserts himself. He is a recognized institution, and as such must be treated with respect. Most medical men have acted in this capacity for a longer or shorter period before settling down in practice; some continue to earn their livelihood for years by acting for other practitioners. The locum tenens may be classified as good, bad, and indifferent. The absolutely bad ones are few and far between, and usually speedily disappear from medical circles, for the simple reason that a locum tenens is usually engaged through a medical agent and has to give a reference to his last employer. In most cases a locum tenens who has been selected with ordinary care, paid at a fair rate, and sufficiently instructed in the routine of the practice, is as efficient a substitute for the practitioner as a stranger can be expected to be. Occasionally, indeed, he gives offence to his employer from proving too acceptable to the patients, though the old story of the locum tenens who seriously lessened the doctor's income by curing a number of old chronic cases will hardly pass muster now. Sometimes medical friends practising in the same locality agree to act for one another during absence, and this is perhaps the ideal method when it can be arranged. Few men with large practices venture to go away for a holiday without leaving a substitute of some kind, though I once heard of a medical man who practised in chambers in the City, who was accustomed to leave town for several weeks every summer, and never would leave anyone in charge of his practice, letting his patients go to whom they liked during his absence. Consultants generally ask a junior member of their hospital staff to see private patients for them in the holiday season, and juniors often thus add considerably to their income, as it is not uncommon in such cases to give them a share of the fees instead of paying them at a fixed rate.

Two cases of interest to the profession have just been decided in the law courts. Mr. Allinson's appeal to the Supreme Court to prevent the Medical Council from removing his name from the register and publishing their decision, has been dismissed with costs. Mr. Allinson must therefore submit to the Council's ruling, unless he is prepared to take the risk and incur the great expense of taking the matter to the House of Lords. He will probably hesitate to do this, especially as, although we profess to put down illegal practice, there is nothing whatever in our law to prevent his carrying on his practice as before, provided he does not call himself a medical man and assumes no medical titles.

The other medico-legal case concerned the Fulham case of scarlet fever, in which there was such a conflict of medical opinion as to the nature of the illness. The mother of the child appealed against the decision of the magistrate, whereby she was fined ten pounds, with two guineas costs, for obstructing the execution of the magistrate's order for the removal of her child to the Western Fever Hospital. In view of the special circumstances of the case, and the conflicting opinions of the medical men called to give expert evidence, the Home Secretary had remitted the fine and costs. The appeal therefore involved no further practical issue in the present case, and interest vanished from the case entirely when the appellant stated through her solicitor that she would withdraw her appeal if no costs were asked for against her.

The Mattei bubble has at last burst. The Mattei treatment was boomed into notoriety some months ago by Lady Paget, who wrote an article in its favor in a review, which was followed by another by Mr. Stead in his organ, *The Review of Reviews*. Mr. Stead took up the subject with his usual enthusiasm, and proposed that the value of the Mattei treatment should be properly examined by the exhibition of the Mattei remedies, to test cases of cancer under medical supervision. A medical committee was accordingly formed, and the result is what might have been expected. The patients selected as test

ises have gradually got worse, no case being cured or ven markedly benefited. The bubble has finally burst the withdrawal of the Matteists from the experiment.

A link with the past is severed by the death of Mr. muel Armstrong Lane at the advanced age of ninety. Ir. Lane was a surgeon of the old school, and was both skilled anatomist and a dexterous operator. His surcal writings were not numerous, but he edited the new lition of "Cooper's Surgical Dictionary." He was unccessful in his candidature for an appointment at St. eorge's Hospital, so he founded the Grosvenor Place chool of Medicine, a school with which many teachers f note were associated, and where many men who have nce risen to distinction received their medical educaon. He was selected as the senior surgeon to St. lary's Hospital when that institution was founded, in 843, and it is in connection with that institution that he ill be best remembered, for the name of Lane has been onnected with the hospital ever since. A younger rother, Mr. James R. Lane, subsequently joined the surical staff, and his son, Mr. J. Ernest Lane, is at present he junior surgeon.

New Instruments.

A MODIFIED GOTTSTEIN'S CURETTE.

By CARL E. MUNGER, M.D.,

CLINICAL ASSISTANT MANHATTAN EYE AND EAR HOSPITAL, THROAT DEPARTMENT, NEW YORK.

THOSE who have used Gottstein's ring knife for the removal of "adenoids" from the naso-pharynx, have found it of the greatest convenience and utility, by reason of its ease of introduction and manipulation. It is an instrument which can ordinarily be used without the aid of anæsthesia, and the further advantages possessed are its adaptability to patients of all ages, the absence of danger of harming surrounding tissue, and the thoroughness of removal of the adenoid vegetations.

In a recent number of the RECORD is an excellent article by Dr. Frank E. Miller on the "Removal of Adenoid Vegetations from the Vault of the Pharynx" by "Gottstein's new improved curette." A still further modification of this most useful instrument, and one which I have found to be in every way satisfactory, is reached by having the instrument so made that, while preserving the general contour of the "improved Gottstein," the distal portion of the ring, instead of having a slightly convex or nearly flat surface, has its form so changed that the ring presents a heart shaped appearance, as seen in the accompanying cut. The advantage of this is that the curette can be made, as it were, to straddle the posterior edge of the nasal septum and by so doing allow the two wings of the "heart" to reach into the choanæ. By this means the curette can be brought farther forward and the space more thoroughly cleared than by any other form of the ring-knife.

A somewhat similar instrument was recently shown by Professor Adam Politzer, of Vienna, at a meeting of aurists in London, but, so far as I know, this shape has not been used in this country.

I have found this modification of Gottstein's "ring messer" or curette to be very satisfactory in the removal of adenoids, and take great pleasure in recommending it to those using like instruments. This form of the curette can be found at Meyrowitz Bros., instrument makers, New York.

The International Congress of Anthropology was held in Ulm, Bavaria, during the week ending August 6th.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 27, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	42	14
Scarlet fever	40	4
Cerebro-spinal meningitis	1	1
Measles	73	8
Diphtheria	58	16
Small-pox	11	1
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

The Efficacy of Medical Parliaments.—The Berlin correspondent of the *Occidental Medical Times* writes: Five years ago the institution of Medical Councils (*Aerztekammern*) was founded in Prussia, as a sort of special parliament for the medical profession of each of the provinces, for the purpose of discussing all important questions pertaining to medical affairs, both scientific and civic. It was hoped that these assemblies would prove of great value as the official mouth piece for the wishes of the whole body of physicians throughout the land, looking after our special interests, giving advice to the government authorities on numerous important questions, etc. The representatives are elected by general ballot. Hitherto they were devoid of any executive powers whatever, but it is now proposed to invest them with certain judicial and punitive functions for the furtherance of medical ethics and etiquette, in analogy to the similar institution already existing for lawyers in Germany; a sort of court of honor which shall put down all dishonorable dealings and such infringements of the ethical code as do not come within the range of civil law. The proposal has excited a most animated discussion, both in the Berlin Medical Society as well as generally in all larger cities. In Berlin the measure was very heartily condemned by a large majority, while in other parts a great number of votes are recorded in its favor. There can be no doubt that there is a large field for amelioration among medical practitioners, but it appears questionable whether this is the right way to insure it. Altogether, as regards the work done by the *Aerztekammern*, the opinion is rather prevalent that their utility is somewhat problematic. The organizers and adherents were, therefore, all the more gratified and fortified by the resolution recently accepted in Austria of introducing there a similar arrangement; a measure which was supported in the upper house by Billroth in most enthusiastic and hopeful terms. After all, it seems not improbable that the contemplated innovation will take place in Germany sooner or later.

Cimicifuga in Uterine Disorders.—Dr. Boardman Reed says: Ten to thirty drops of the fluid extract after meals are used to cure seminal emissions. This has rarely failed in my experience. Half a grain to a grain of the resinoid, cimicifugin, twice a day, has occasionally been found useful in conditions of nervous depression, hysteria, and incipient melancholia. Five to twenty drops of the tincture, several times a day, have proved very helpful in scanty menses, especially in maiden ladies; but if repeated as often as every three hours, even, are likely to cause severe headache. This untoward effect I have never seen from the largest doses, such as half a drachm or drachm of the fluid extract three times a day. Such doses are said, however, to produce headache sometimes. Very small doses, as one-quarter of a drop up to one drop of the ordinary tincture, repeated every one or two hours, will often promptly relieve a frontal headache

due to mental fatigue, or any kind of a headache resulting from pelvic congestion at the menstrual period in women. The same doses are often efficient in preventing abortion when threatened from weakness or passive congestion of the uterus, or from habit at a certain stage of pregnancy. Two or three drops of the tinctures of cimicifuga and gelsemium—sometimes one drop of each—every hour or two, are among the most certain means of bringing on the menstrual flow when delayed by passive congestion, cold, grief, or other similar cause, and acts similarly with the lochial discharge after parturition. Dragging pelvic pains arising from the same causes may be relieved by the same combination.—*American Therapeutist.*

Twice too Many Doctors in the United States.—Up to the present time the number of medical colleges has increased out of all proportion to the increase of population. Of 130 schools, less than a dozen are endowed. The number of practitioners is greatly in excess of the legitimate demands of the people. We are reliably informed that in the decade ending with the year 1890 the colleges of the United States matriculated 115,355 students, and graduated 39,996. This is an average of 4,000 yearly—in my opinion more than twice as many as the requirements of the people demand. As a final argument in behalf of adequate medical legislation, I beg to submit the following statistics, based upon the proportion of physicians to the inhabitants in a few of the European countries :

Ratio of Physicians to Population.

Sweden	1 to 7,000
Italy	1 to 3,500
Germany	1 to 3,000
Austria-Hungary	1 to 2,400
France	1 to 2,000
United States	1 to 600

—Dr. Millard, in *Medical News*.

Southern Medical Education.—The *Atlanta Medical and Surgical Journal* has patriotically started upon the task of awakening Southern medical colleges to the sense of their unfitness. It publishes this list of applications for licenses before the Medical Boards of Virginia and Alabama :

Whole number applied	647
Whole number granted	559
Whole number rejected	88
Percentage of rejections	13.50
Percentage of rejections of graduates Western Medical Colleges	19.40
Percentage of rejections of graduates Southern Medical Colleges	13.01
Percentage of rejections of graduates Northern Medical Colleges	9.45
Percentage of rejections of non-graduates	28.57
Percentage of rejections of graduates (College unknown)	33.03
Percentage of rejections of foreign graduates	0.00

Antisepsis in Typhoid.—Among forty four cases of typhoid fever one half were treated antiseptically, the other expectantly, by Dr. R. Caton (*British Medical Journal*). Here is the result :

	Deaths.	Days of fever.	Days of relapse.	Days in hospital.
Expectant treatment	4	37.9	9	52
Intestinal antisepsis	....	25.3	1 8	46

Dr. Calvin says : "Watching these cases from day to day, I have been much impressed by the apparent good effects of the intestinal antiseptic treatment. It is obviously a rational method. There is considerable evidence that such bodies as chlorine, creasote, naphthalin, iodine, iodoform, and alpha- and beta-naphthol are destructive to septic and poisonous compounds and organisms found in the intestinal canal. It is, therefore, antecedently probable that they would be of service."

Dr. Behring on Blood-serum Therapeutics.—Dr. Behring, of Koch's Institute for Infectious Diseases, well known for his studies on immunity against traumatic tetanus and diphtheria, has published a treatise on the practical aims of blood-serum therapeutics, and the methods of producing immunity, in order to obtain medicinal serum. He endeavors to prove that the blood-serum of animals rendered immune by treatment with cultivations acted on by trichloride of iodine cures other animals infected by the disease and renders healthy ones immune. He has applied this method with success against traumatic tetanus and diphtheria, and now states that one of his fellow-laborers has been equally successful in diseases caused by streptococci. All these results have been obtained by experiments on animals, but Behring's final aim is to find a new means of combating diphtheria, tetanus, etc., in the human body, and he indicates the way to that great end, admitting, however, that it is a difficult and especially a very costly one—too costly for individual investigators or even institutions to enter on without ample pecuniary aid. In the second part of his treatise he criticises other methods of producing immunity. The treatise is published by Thieme, of Leipsic, and its title is "Die praktischen Ziele der Blutserum-Therapie und die Immunisirungs methoden zum Zweck der Gewinnung von Heilserum."

Asthenia from Child-bearing.—J. G. Perry (*New York Journal of Gynecology and Obstetrics*, April, 1892) endeavors to show, from an analysis of seven cases under his care, that in certain women there is a predisposition from unknown causes to yield their vitality in the natural processes of child-bearing in such a manner as to interrupt the retrograde metamorphosis or involution of the pelvic cellular tissue independent and apart from the muscular fibres, and that any interference with this metamorphosis tends to atrophy and fatty degeneration, which cannot be arrested by any known method of treatment. From this atrophy the pelvic organs and those above the pelvis lose their proper support, and provoke certain sensations and mental phenomena. Dragging pains, abdominal cramps, and pain on walking are the chief symptoms. Great mental depression is frequent. Plastic operations and massage prove unavailing; indeed, Perry considers that many of these cases do not yield to any form of treatment. These patients are, of course, quite unfitted to bear more children.

THE ETIOLOGY OF LEPROSY.

By GEORGE L. FITCH, M.D.,

FORMERLY MEDICAL SUPERINTENDENT OF KALAWAO LEPER SETTLEMENT, ISLAND OF MOLOKAI, HAWAIIAN ISLANDS; ALSO OF KAKAAKO BRANCH LEPER HOSPITAL, HONOLULU; AND PHYSICIAN AND SURGEON IN CHARGE OF GOVERNMENT FREE DISPENSARY, HONOLULU.

WHAT is leprosy, and what causes it? The answer, I believe, is: A fourth stage of syphilis, which stage occurs epidemically in races virgin to syphilis, or sporadically in persons whose systems have reverted to a condition virgin to the disease, and occurring also in those presenting a distinct neurotic taint, and whose habits have been such—in regard to food-supply and manner of living—as would without the before stated conditions produce ordinary scrofula.

The effects which follow the introduction of a disease into a race for the first time have been but little studied, and that individual members of a race can revert to a condition virgin to any disease is an idea which, I believe, has never before been advanced. Yet, to my mind, if a person can come into this world a subject "of inherited immunity" from any disease, or with the effect of any disease mitigated by reason of his ancestors having been repeatedly subjected to its influence, the converse of the proposition must also hold true, that a person's ancestors having escaped contamination for generations, a period will certainly appear when the descendants of such ancestors will again be in a condition where their animal economy will be virgin to such disease. Pasteur's experiments have taught us that the virus of disease may be both diluted so as to cause mild, and intensified so as to produce malignant, forms. Do we not here touch on a law of the utmost importance in relation to all maladies?

As to what follows the introduction of various forms of disease among virgin races, I wish to quote from authorities and present instances. Gee[1] quotes, with approval, the words of Trousseau: "No physician has ever seen a child who has died of chicken-pox." If the gentlemen who wrote those words had been on Bear River, in Humboldt County, Cal., in the year 1868, they would not have written as they did. An epidemic of varicella which swept over that region at that time was no more hurtful to the whites settled there than the writers quoted state it to be, but in a rancheria of Digger Indians in the neighborhood there were not enough inhabitants left alive to bury their dead—all swept away by this, to them, fell destroyer. The ravages of small-pox and measles among the aboriginal races of various parts of the world, when first subjected to the effects of these maladies, are well known, and, further on, I propose to introduce evidence as to what follows the introduction of syphilis among such peoples. Quoting from authorities on this subject,[2] J. C. White, M.D., says: "Nor can we overlook the proclivity of all epidemic diseases to extraordinary manifestations of virulence in insular nations not previously protected by gradual inoculation." Bumstead and Taylor say:[3] "In all countries where syphilis has existed for many years its course is much less severe than it was originally, and the disease of to-day is really mild in comparison with what it was when it was first observed in Europe. It is well established that syphilis is especially malignant when appearing for the first time in a community. Numerous instances were recorded of the frightful ravages produced by it under such circumstances. The initial lesions are said to have been phagedenic and to have been followed by severe secondary symptoms; while necrosis and visceral lesions were almost invariable and precocious. This malignancy gradually diminishes in successive generations, until a comparatively mild form of the disease is established. It seems that a certain protective influence is secured to progeny by the occurrence of syphilis in their ancestors, which, although not conferring absolute immunity, decidedly modifies the course of the disease.

Thus our ideas of the nature of syphilis are free from that fear with which our forefathers were accustomed to regard it, and we no longer look upon it as "an incurable disease." Jonathan Hutchinson, F.R.S., in "Reynolds's System of Medicine," edited by Hartshorne, vol. i., p. 427, says: "Fourth, of yet wider importance is the question as to the *influence of disease in the parent in affording protection, partial or complete, to the offspring.*" If we grant, as we must, the two postulates—first, that syphilis is transmissible to offspring, and, second, that it is protective for a certain time against second contagion, then we are obliged to admit that just as the disease itself may be transmitted so may the immunity which it affords. Here, again, we have, as yet, very little clinical evidence on which to build, but what we do possess certainly favors the view that those who have suffered severely in infancy from inherited disease are, to some extent, protected. In the history of congenital syphilis, however, nothing is more common than to meet with such cases in which the eldest child in a family suffered severely in infancy, the second slightly, the third still more slightly, and the others not at all. I have at present several families under observation in which this has been the case, and in which all the children have lived, and the intervals between them are but short. The younger members of such families often appear to be in robust health. Now, if in such cases the oldest enjoys immunity, probably the second also does so in some degree, and so on through the whole, the degree of protection diminishing in ratio to the distance from the original taint. Do we not here touch upon a law of the utmost importance, not only in respect to syphilis, but to its congeners also? Is it not probable that a very considerable portion of the community, being the descendants of those who have suffered, enjoy, in a certain degree—infinitely slight in many but powerful in others—immunity from further attacks? The manner in which a slight degree of inherited immunity would become manifested would probably not be in the entire escape of the contagion, but in the production of a much milder form of the disease. This is what occurs in cases of small-pox after vaccination, or after a previous attack of the true disease, and, indeed, in second attacks of any of the specific fevers. It is surely impossible to believe that the constitution of a person who has passed through the stages of any of these diseases ever again returns into precisely the same condition in relation to the virus in question that it occupied before; and it is equally inconceivable but that some share of this peculiarity shall be transmitted to offspring. A child born of parents neither of whom is liable to small-pox or syphilis, as the case may be, must be in a different position, as regards those diseases, from the child of parents both of whom are liable. In like manner, a half result ought to be ex-

[1] Reynolds's Practice of Medicine, vol. i., p. 127.
[2] Pepper: System of Medicine, vol. i., p. 788.
[3] The Pathology and Treatment of Venereal Diseases, p. 496.

pected where one parent is exempt and the other liable. Now it is a matter of well-known observation that any specific disease will be especially severe when imported into a community previously free from it. The ravages of small-pox in a virgin race are something far beyond what is ever known in a community long accustomed to the disease. There are also good reasons for believing that syphilis has become, during the last two centuries, a milder disease than it was when it first invaded Europe. This amelioration we may most satisfactorily explain by recourse to the hypothesis above suggested.

Now turning to the second point, the system reverting to a virgin condition. I quote from "Genito-Urinary Diseases with Syphilis," by Van Buren and Keyes, p. 539: "In 1865, in the cutaneous wards of St. Louis Hospital, under Professor Hardy's care, were two cases, man and wife. The man had severe malignant syphilis, with large gummy deposits in his skin, some of them ulcerating, all occurring within a few months after the chancre. She had a very mild papulo-erythematous syphilide, bearing none of the characters of malignancy. The woman from whom the man acquired his disease was sought and found. She, also, had a simple case of ordinary mild syphilis. The poison in these three cases was identical, handed directly from one to the other, but the results were so widely different that it would have been hard to convince a layman of their identity of origin." What the idiosyncrasy is which makes syphilis bad in one case and light in another cannot be affirmed. Does not the theory of one's system reverting to a condition virgin to disease, or "inherited immunity," for the first idea is the complement of the last, explain the case quoted and similar cases; that is, the varying degrees of the severity of diseases, in a manner not otherwise explainable?

I have no other case at present to quote on this point, as I am not aware that the subject has ever been even mentioned by any previous writer.

Now let us inquire more closely into what really happens on the introduction of a disease to a virgin race. Turn we to an old volume, entitled "Narrative of a Voyage Performed by Captain Cook and Captain Clarke in His Majesty's Ships Resolution and Discovery:"[1] "Many who were alongside in their canoes pleaded hard to come on board, but Captain Cook had given strict orders, previous to his anchoring, not to suffer a single woman to be admitted into the ships, as there were several people in both who still had the venereal disease. But notwithstanding every precaution, many of our men contrived to have connection with them, in consequence of which we found this terrible disorder raging among them when we arrived there the second time."

From Jarvis's "History of the Sandwich Islands," page 108: "During the visit, which lasted but a few days, the commander manifested a laudable humanity, in endeavoring to shield the population from the evil effects which so inevitably result from connection between foreign seamen and the native females. But his efforts were in vain. If the discipline of his own crew could have been strictly enforced, the eagerness of the women was not to be repressed. The native history thus accounts for its commencement, by which it will be seen that however praiseworthy the motives of the commanders of those expeditions may have been, the licentious habits of the natives themselves were sure to counteract them." Further on Jarvis says of a female chief: "Accordingly she sent her own daughter on board, who returned with the seeds of that disease, which so soon and so fatally spread itself throughout the group." That syphilis should so soon have become almost universal will not seem strange when we consider their habits. Jarvis says on this subject, page 73: "The ceremonies observed on the death of any prominent personage were extremely barbarous. . . . Gambling, thefts, and murder were as open as the day; clothing was cast aside as a useless encumbrance; drunkenness and promiscuous prostitution prevailed throughout the land; no women, except the widows of the deceased, being exempt from the grossest violation. There was no passion, however lewd, or desire, however wicked, but could be gratified with impunity, during the continuation of this period, which, happily, from its own violence, soon spent itself. No other nation was ever witness to a custom which so entirely threw off all moral and legal restraints, and incited the evil passions of men to unrestricted riot and wanton debauchery." On page 90: "As a general thing, there was no such sentiment as chastity; sensual desires were gratified as choice prompted; their only rules being their wishes, modified by jealousy or fear. Visitors of equal or greater rank than their hosts were accommodated with women as a necessary exercise of hospitality. . . . The family alliances, or more properly speaking, connections, were of the most intricate and shocking nature. Custom obliged the highest chief to marry the next in rank, consequently brothers and sisters, own cousins, nieces and uncles, nephews and aunts, frequently exercised toward each other the relations of husband and wife."

Among a people with habits and customs such as these syphilis was introduced, as we have just seen, by Captain Cook and his associates, in 1778. Let us note the results:[1] "Dr. Chapin, in the *American Journal of the Medical Sciences*, says: 'With such an introduction the venereal disease has for the past fifty-seven years continued to spread and increase, perpetuated and extended, too, by almost every vessel which touches at the islands, till words fail to express the wretchedness and woe which have been the result. Foul ulcers, of many years' standing, both indolent and phagedenic, everywhere abound; and visages horribly deformed, eyes rendered blind, noses entirely destroyed, mouths monstrously drawn aside from their natural positions, ulcerating palates, and almost useless arms and legs, mark most clearly the state and progress of the disease among that injured and helpless people.' Rev. Artemus Bishop remarks: 'Their previous looseness of morals formed a ready conductor for the disease, which was introduced by the first ship which touched here; and, from the account given by the natives themselves, the consequences were incalculably more dreadful than had been feared by Captain Cook and his associates. The deadly virus had a wide and rapid circulation throughout the blood, the bones and sinews of the nation, and left in its course a train of wretchedness and misery which the very pen blushes to record. In the lapse of a few years a dreadful mortality, heightened if not induced by their unholy intercourses, swept away one-half the population, leaving the dead unburied for want of those able to perform the rites of sepulture.'"

Among the documents sent out by the Hawaiian Government in 1886 is one bearing the title of "Leprosy in Foreign Countries." On page 172, in the report of a "Discussion before the Academy of Medicine, Paris, on the Transmissibility of Leprosy,"[2] "M. Jules Rochard observed that, in his opinion, it was not certain that leprosy had been imported into the Sandwich Islands in 1848, since M. Quoy had seen it there since 1819, when he made his voyage of circumnavigation."

The diary of Rev. Charles Stewart, one of the early missionaries to Hawaii, under date of May 22, 1832, says: "Not to mention the frequent and hideous mark of a scourge which, more clearly than any other, proclaims the curse of a God of purity, and which, while it annually consigns hundreds of this people to the tomb, converts thousands, while living, into walking sepulchres, the inhabitants generally are subject to many disorders of the skin. The majority are more or less disfigured by eruptions or sores, and many are as unsightly as lepers. The number of either sex, or of any age, who are free

[1] London, 1782, by W. Ellis, Assistant Surgeon to both vessels, vol. i., p. 170.

[1] New York Journal of Medicine for March, 1855. Article by L. H. Gulick, M.D., on Climate, Diseases, and Materia Medica of the Hawaiian Islands.

[2] Le Temps, Paris, October, 1885.

from blemishes of any kind is very small, so much so that a smooth and unbroken skin is far more uncommon here than the reverse is at home."

Further on Mr. Stewart says: "July 4, 1823. Indeed, we seldom walk out without meeting many whose appearance of misery and disease is appalling, and some so remediless and disgusting that we are compelled to close our eyes against a sight that fills us with horror. Cases of ophthalmic scrofula and elephantiasis are very common." Commenting on these quotations, Arthur Mouritz, formerly physician to the Kalawao Leper Settlement of Molokai, Hawaiian Islands, says, in the "Appendix to the Report on Leprosy of the President of the Hawaiian Board of Health for 1886:" "That the author means elephantiasis græcorum, or true leprosy, and not elephantiasis arabum, is quite apparent. The appearance of the latter has no parallel with that of the former. And, again, elephantiasis arabum has never been known to have existed here. It remains, therefore, that the elephantiasis of the passage is true leprosy, such as prevails at the present time among the islands of the group." In these conclusions of Dr. Mouritz's I fully concur. In a former paper, which was published in the *Pacific Medical and Surgical Journal* and *Western Lancet*, under date of October, 1885, I have shown that leprosy existed throughout the entire Hawaiian Islands in 1835, and from the statements just quoted it would seem to have been present as early as 1819, or forty-one years after syphilis was introduced.

But let us now turn to other quarters to seek enlightenment on this matter. Rev. A. A. Sturges, who went to the Caroline Islands as a missionary in 1851, said to me that on his arrival there he found syphilis, but it was not very common, while now it is all but universal. As whalers began to visit Ponape the disease became more and more common, and worse and worse in its effects. On his first visit there he found cases in which fingers and toes were dropping off; but such cases were uncommon, and, later on, the tubercular form of the disease began to appear. Mr. Sturges never knew a white man to have the disease there until years after it was common among the natives; and not a Chinaman had ever visited the group until years after the natives were extensively affected. The whites first settled there in 1840. Now, Mr. Sturges thinks, about one in twenty of the natives are lepers. In the year 1856 Mr. Sturges first visited the island of Pingalap, lying about one hundred and forty miles from any other land, and found the people of that island, as he expressed it (the inhabitants were naked savages, giving the fullest opportunity for examination), the cleanest-skinned persons he ever saw in his life—this expression he repeated twice to add to the emphasis. In 1860 Mr. Sturges visited them again. During this interval of four years, some whalers had called, and on his second visit Mr. Sturges stated that he found them terribly diseased with syphilis. He described their condition at this time as truly pitiable. In 1871 Mr. Sturges visited them for the third time, and found leprosy prevalent. This account is from notes of an interview with Mr. Sturges, held in Honolulu, October 28, 1885.

Still again, on page 254 of a book called "New Zealand and its Inhabitants," by Rev. R. Taylor, I find this written:

"Some of these persons were afflicted with insanity and partly leprous. . . . Scrofulous diseases are now general among the natives; originally introduced by Europeans, they are now naturalized in the system, and have become a chief cause of mortality among them."

September 11, 1890, I saw a Digger Indian squaw at Ukiah, Mendocino County, Cal., who was a leper. Both her thumbs had dropped off, at or near the metacarpo-phalangeal articulation. The middle finger of the left hand had lost the bone at the first joint, and the nail was gone. The rest of the fingers were clubbed, and the nails were mere rudiments. The right hand was further advanced, the fingers being all mere stubs. Above the wrist, on the inner aspect of the forearm, was a scar reaching half way to the elbow. The entire palmar surfaces were of a dirty white color. At the inner part of the left eyebrow was a macular spot, showing a pink color instead of the dark natural hue; this spot was about the size of a nickel. Both lower eyelids were ectropic; the left foot was greatly swollen, and on the plantar surface was a perforating ulcer fully two inches in diameter. I could not succeed in getting any more of an examination. She was sitting on her right foot, and positively refused to let me examine her further. She was in a rancheria by the side of a moribund man—a patient with double pneumonia, and she and some twelve or fifteen more were waiting for the breath to leave his body to begin their death-wail. I did not see any other cases of leprosy among these persons, but, of course, could not make a close examination. In December, 1870, I amputated the arm of a leprous squaw in Humboldt County, Cal. At the time I did not recognize the disease, but, on becoming fully acquainted with it in Hawaii, there could be no doubt but that which I thought was an old scrofulous sore hand, for which I did the operation, was leprosy. Dr. L. E. Meeker, of Brooklyn, N. Y., formerly of Arcata, Humboldt County, Cal., assured me that he had an Indian there who had leprosy. He (Dr. Meeker) also did not recognize the disease as leprosy until familiarity with it in Hawaii enlightened him. I have heard of other cases among the Digger Indians where fingers and toes dropped off, but on account of the patients not having been seen by a medical man, make no account of them. A systematic inspection of the Indians of the Coast would be very desirable in this matter.

Turning from the general view of the subject to special cases, the histories of some of which came under my observation in Hawaii, may help to a clearer understanding of our study.

Case I.—Israel F——, a German, aged fifty-six, first came under observation in January, 1882, when he consulted me about an anæsthetic spot on his forearm. His statement was that in November, 1858, he had a single sore on his penis after illicit intercourse with a native woman. No clear history of symptoms—except general ill health which before had been good—until 1862, when severe nocturnal headache set in; this continued almost without cessation for six years. It was distinctly nocturnal, beginning after he would get warm in bed and continuing until near morning, when he would get a short period of sleep. During this same time his mouth was drawn around toward the right ear—paralysis of facial muscles. After enduring his sufferings for six years, during which time he never had any regular medical advice, he left Hawaii and came to California, where, after a year spent in the mountains, he improved somewhat and then returned to Honolulu, but he was never as well as he had been previous to the time of having the chancre. In January, 1881, he was vaccinated in the usual place on the left arm with bovine virus obtained from Martin of Boston. There was no doubt about the source of the virus, so there could be no chance of infection from that direction. Yet within three weeks after the vaccination, which took well, an anæsthetic, or rather an analgesic, spot appeared on the flexor aspect of the left forearm, just above the carpal region, about two inches wide by four long. Gradually afterward his face took on the flushed, swollen appearance of leprosy. The little finger of the right hand, on the external aspect, and the hand, also, in the same region, became extremely hyperæsthetic, so much so that even drawing a feather lightly over the surface caused him much pain. Examination, when he came to me, showed marked enlargement of both epitrochlear glands, slight of posterior cervical chain, left side, and of "Ricord's pleiad," both sides. While under my observation his face became greatly swollen, taking on the well known leonine appearance, the nocturnal headache returned by

spells, and the mouth was again drawn around toward the right. Notice of the latter event brought out the fact of its previous existence. A large abscess formed just posterior to the upper portion of the sterno-cleido-mastoid muscle, which was long in healing. He became an inmate of the Leper Hospital, near Honolulu, where he finally committed suicide.

Case II.—M——, was a native of New York, which State he left to escape the attentions of the Sheriff, and, after a period of wandering, brought up in Honolulu. There he cohabited with two native women, sisters. By one he had one child, by the other, two. F. M——, one of the children, when about twenty years of age, had a sore on his penis after illicit intercourse with a native woman, followed by general syphilis. While in the early secondary period he married a half-caste girl, whose father showed plainly the marks of ancient syphilis. The daughter who married F. M ——, had, when about fifteen years of age, an illegitimate child by a physician who formerly lived there. When the family came under my observation, in 1882, this illegitimate child was twelve years of age. Below her left knee, on the anterior surface of the leg, and just above the right mamma, were spots, each somewhat more than an inch in diameter, which presented the appearance described by Bumstead and Taylor in their work, "Venereal Diseases," page 605, under the heading, "The Pigmentary Syphilide." They present the peculiar appearance aptly conferred by Fournier to a "net-work of lace with large meshes." Besides this she had marked epitrochlear and post-cervical adenopathy, but no distinct symptoms pointing to leprosy. The children of F. M—— and his wife, four in number, each, in succession, as soon as the permanent teeth appeared, became lepers. The eldest, about ten years old when I first saw her, was a marked case. The next was not at first as clearly marked, but soon she also became a bad case. The third soon followed in the same footsteps, and, in December, 1885, when I left Honolulu, the youngest child, a boy about six years old, was just showing unmistakable signs of the dread plague. F. M—— was an opium-eater and had been arrested for forgery and I know not how many other offences. He, his wife, and the illegitimate girl, all lived with the leprous children, all occupying one bed—mats spread on the floor—where they all bunked promiscuously, having but one room for all purposes. They all ate from the same dishes, and the two eldest girls wore the same clothes. This was continued for years, yet the parents and half-sister escaped the disease. Owing to the father's bad habits, the family lived in want of the commonest necessities of life, having hardly food enough to support nature, and that of the poorest quality. Can anything be clearer than the fact that the leprosy here was the result of the mother's inherited syphilis and the father's acquired, together with the wretched condition of the father's nervous system and the family surroundings?

Case III.—C. S——, native of Pennsylvania, aged forty-two, came under observation July 6, 1882. He gave the following history: In 1867, while residing in Tahiti, after intercourse with a native woman, he had a single sore on his penis just back of the corona, in the sulcus. This caused him but little pain and there was no discharge from it. It was followed by a bubo which did not suppurate. In 1868 he went to the Island of Borabora, and while there discovered that the middle finger of his left hand was analgesic, and during the latter portion of the year he had bad spells of chills and fever, and bones paining him all over, which he took to be rheumatism. In 1874 he was at Palmyras Island, where he was seen by Dr. White, of the United States Navy, who told him he had syphilis. Dr. White came to Honolulu, where I saw him, and he told me that he remembered S—— well, and in 1874 S—— was suffering with syphilis. During all these years S—— was leading a drunken, dissolute life, and had no treatment for his disease. He stated that his left ear became sore and a portion of the lower lobe sloughed off. He accounted in this way for its being much smaller than the right. It was also analgesic. His left testicle also swelled and became as large as a goose egg, and very hard. In 1877 some of the toes on his left foot became analgesic, and finally the entire foot was in the same condition. Later, the right foot and leg up to the knee had intermittent spells of numbness. In 1878, while in Honolulu, he was recognized as a leper and sent to Kalawao Leper Settlement on the Island of Molokai. When I first saw him the hair on his head was thin, generally, and eyebrows gone; whiskers very scant. There were leprous tubercles on his face and breast, and a spot about eight inches in diameter above and to the left of the umbilicus, which was of a nearly dead white color surrounded by a bronzed or rather raw-ham-colored areola. This spot was analgesic. Both hands and arms half-way to the elbow, and the feet and legs nearly to the knees, were the same. He was thin and cachectic, presenting in a marked degree the appearance commonly known as "Buzzard's muddy pallor." Much of the time he was confined to his bed and seemed about to die. Under the use of fuming nitric acid, ninety minims a day, well diluted, he gained thirty pounds weight in a short time, but the analgesia and tubercles remained much the same. In March, 1884, he had an attack of iritis of the right eye, which had been progressing a week before I saw it. The iris was grass green, and belladona produced only a very slight and irregular dilation accompanied with much pain, synechia having formed. The pain rapidly disappeared under the use of small and oft-repeated doses of calomel and opium, but sight in that eye was limited to perception of light. A few months later the left eye became similarly affected, when I had him removed to Kakaako Hospital, Honolulu, where Dr. J. Brodie did a double iridectomy with good results for the time, but the incision in the iris soon blocked up with exudative material and a second operation became necessary, which left him with sufficient vision to find his way around the hospital yard. A circular aperture formed in the septum nasi large enough to admit the little finger. Afterward, ulcers appeared on the right side of his face, from the mouth back to the ramus of the inferior maxilla, which became covered with thick oyster-shell-like crusts, and his general health again broke down. In 1883 he showed many of the symptoms of locomotor ataxia. Standing with his eyes closed when his heels were together was very difficult. He was greatly troubled with darting pains, felt more especially in his extremities. His sexual desire disappeared, and it was difficult for him, without seeing them, to hold things in his hands. This was probably caused, to a large degree, by his loss of the sense of touch. He stated that when he put his hands in his pocket for anything he was unable to tell from the sense of touch whether he had his penknife or a ball of wool in his hand. In walking he could not feel his feet touch the ground, so that it was difficult for him to walk after dark. In these particulars he was not different from other lepers having analgesic symptoms well marked. In fact, many of the ear-marks of leprosy are the same as those of locomotor ataxia, with the exception that nature seems hardly capable in leprosy to carry out the nervous symptoms to the same pitch of development.

Case IV.—K——, male, aged forty-six, had non-suppurating buboes followed by sore throat and severe nocturnal rheumatism. Kamalii, his wife, aged forty, contracted syphilis shortly after marriage, which occurred twenty-one years before. Their first child was still-born. The second had destructive ulceration of the mouth which left the lower jawbone exposed—this child died, aged six months. Third child had sore nose and snuffles—died at two months. Fourth child—one eye ran out and it had snuffles; lived two weeks. Fifth child—still-born. Sixth child was given away to a friend and lived eight months; no history (natives frequently give their children away). Seventh child died at one month; could

never eat; had snuffles and shrunk away and died. Eighth child given away; died at one month. Ninth child also given away; died at two weeks. Tenth still-born. Eleventh labor, twins, both children girls. The first, born during the night, died at sunrise. The second had snuffles, but survived; at the approach of puberty, when she was over twelve years old—one cheek began to get red and swollen as if she had received a blow, although she had not met with any injury. Then papules, gradually increasing in number, began on the cheek, and soon by aggregation, formed a plaque which involved the entire right cheek and extended to the bridge of the nose. There was another of these plaques on the left leg, on the anterior aspect, just below the knee. I watched the case for several months and saw a few papules on the left forearm grow in number, coalesce and form a plaque. The parents told me those on the cheek and leg began and reached the proportions they exhibited when I first saw the case, in the same way. They were of a dull red-brown color, hard and brawny to the touch and insensitive to the prick of a pin. The papules were of pin-head size, acuminate, hard, and a slight scurf was on each, so, as they became numerous enough to form a plaque, the surface was slightly furfuraceous. The girl was a leper.

Case V.—Liwai, aged sixty-three, a native, came to the Government Dispensary in Honolulu with syphilitic necrosis of the lower jaw. With the kind assistance of Dr. G. Ollino of San Francisco, then on a visit to Honolulu, I removed the sequestrum, which involved the parts from the symphysis back to the ramus. The history the patient related was, that in early manhood he contracted syphilis from a native woman, and, shortly afterward, while his disease was in an active condition, he married. The first child, a son, had sores break out on the hairy scalp and over the buttocks, when he was six weeks old. He was taken to Dr. Hillebrandt, who applied some dark colored ointment and kept the child under treatment more than a year. It lived to grow up, and, at the time the father was under my care, was over thirty years of age. He, the son, had late syphilitic ulceration of the fauces, which I cured with potassium iodide. The next child born to Liwai had the same trouble as the first, but, as the parents at that time were very poor, they did not seek medical assistance and the child died when about six months old. The third child seemed healthy until he was about fourteen years of age, when he became a leper and, in 1882, was as bad a case as I ever saw. The fourth child born to this couple seemed healthy until he was six years of age, when he also became a leper and died with the disease before the third child developed it. The fourth child was given to friends and never had any communication with the third and only saw him a few times and never after the fourth became a leper. The parents went to the leper settlement of Kalawao to live with the third child, and remained there, living with him in a little one-roomed cabin until the father came to Honolulu for treatment for his necrosed inferior maxilla, and after his recovery returned to the settlement. The mother, during her husband's absence, picked up a lover of about the same age as her eldest son and left her leprous son to care for himself until his father returned to him. Neither of the parents showed a trace of leprosy although they had lived with their leprous son for more than five years after he became a leper. Here let me quote again from the article on "Constitutional Syphilis," by Hutchinson, p. 444, "Inherited Disease:"

"*Primary Stage.*—The infants usually remain without symptoms for from one week to three months.

"*Secondary Stage.*—Constitutional or exanthematic. From the age of two to four weeks to the end of the first year. This stage is essentially transitory, and will disappear without treatment, if the child lives.

"*Intermediate Stage.*—Stage of latency. This stage extends from the end of the first year of eighteen months to the second dentition, the time of puberty or even very much later.

"*Tertiary Stage*, or stage of sequelæ. This stage may commence with the second dentition, at the time of puberty or not till much later. Its duration is quite indefinite."

The applicability of the preceding quotation to the series of cases just given is too obvious to require comment.

Now let us consider our subject in still another light—and here I must use, as it will be readily seen I have already, some of the facts I have employed on a previous occasion. The etiology of this disease is so intimately intermingled with the question of contagion that I must rely, to a certain extent, on the same facts to prove my position in either instance, I may therefore be pardoned for calling attention twice to the same series of cases as well as quotations.

On November 14, 1883, I inoculated six lepers with the virus of syphilis, by taking six ivory vaccine points, and scraping off the surface of a mucous patch on the inner side of the lower lip of a native woman. The points were then allowed to dry, and, three hours afterward, I transferred the virus to the arms of six leper girls under twelve years of age. December 14th, following, I repeated the experiment, taking the virus from a hard chancre on the penis of a Portuguese who came to my office. I saw this man in March, 1884, three months later, in the office of a brother physician, and found he was suffering severely from secondary syphilis. The last time I used fourteen points and inoculated fourteen lepers therefrom, but no result followed in any of the twenty experiments. For the suggestion of this experiment I am indebted to my friend, Dr. E. Pontoppidan, of Copenhagen, Denmark. I am not aware that anyone else has ever attempted to inoculate a leper with syphilitic virus. Since coming to San Francisco I have tried, on several occasions, to get the opportunity, but so far without success. If it be eventually established that a leper cannot be inoculated with syphilitic virus, I imagine that syphilographers will need no other proof to convince them of the etiology of leprosy.

Turning now to still another branch of our subject, the neurotic condition of lepers, one illustration will suffice. In 1837 a young couple from one of the New England States settled in Hawaii. The husband was a man of marked nervous erethism; of an excitable, quick nature; a slim, thin figure. He became noted for his eccentricities, and was at one time sent by his friends back to his Eastern home, in hopes that he might regain his mental equilibrium. He came back to Hawaii; became greatly interested in the study of conchology, and died on a trip to the South Seas, as the results of putrid fever contracted by keeping numbers of uncleaned shells in his cabin in the vessel he was travelling in. One of his sisters went insane from a disappointment in love and has been insane all her life. Eight children were born to this couple. The eldest had also a disappointment in love and has always been somewhat of a hypochondriac; the second is of a most irritable, excitable nature, given to outbreaks of wrath on trifling occasions; the third married when twenty-four years of age. When her third child was born she had an attack of puerperal mania, was a raving maniac for seven days; then had erotic desires which led her to strip off her clothes and mounting bareback on a horse to ride wildly across the country and to commit the wildest excesses with chance acquaintances, natives, and Chinese. By the end of a year's time she apparently regained her mental health, and husband and wife resumed their married life, she becoming the good wife and mother she had been previously. Three more children were born to them, making six in all. After the birth of the last, now fourteen years of age, the wife again became insane and has remained so, with occasional lucid intervals since. In 1884, during one of her sane periods, she, with a sister, came to San Francisco, where, coming under medical observation, she was pronounced a leper, and was at once hurried back to Hawaii. On arriving there the entire

family came under inspection. The first of the six children had died in 1879 with typhoid fever; the second, in 1884, some sixteen years of age, was a leper; the third was not a leper, but had congenital absence of the upper lobes of both ears; the fourth was a leper; the fifth was not, but at two years of age had had an attack of infantile paralysis which left the right heel drawn up to the top of the left patella; the sixth was simple minded and a leper. Shortly after arriving back at Honolulu the mother had another attack of insanity and her leprosy disappeared, and has not since manifested itself, although she has had no regular treatment therefor. The father of this family, a very intelligent German, took the second and fourth child who showed the leprosy and came to this coast, the third child, who did not at the time show it, also came here, but lived five hundred miles from his leprous relatives, but, in less than a year, he developed it, and now all three of these children are inmates of a lazaretto where all are improved wonderfully under treatment.

Turning back in our history, the next child born to the New England couple is eccentric; the next was drowned in youth; no history. Next came twins, one died, aged six months. Before his death he had a sore on one carpus which ulcerated through, so that a free passage existed. The other twin grew up, led a licentious life; had an illegitimate child by a native woman. The child, when I saw it in 1881, was a severe sufferer with inherited syphilis.

In the *Medical Bulletin* for March, 1883, J. V. Shoemaker, A.M., M.D., gives us a little of the life history of this second twin. "H. J——, aged thirty-four, was born in Honolulu and had resided there since his birth, with an occasional trip to the States; his parents were Americans, who had emigrated from New Hampshire to that island. His occupation was that of a planter, and he had succeeded in saving sufficient means to enable him to live in comparative comfort. He stated that he had led a very dissipated life until he was twenty-four years of age, especially in promiscuous intercourse, but had never had any venereal disease. Eight years ago, having felt poorly for a time, he noticed a dead spot of skin just above the knee. It spread slowly, and was only about twice as large four years after its first appearance. Six months later he married a healthy native woman, and a weak and puny child was born to them within a year, which lived but a short time."

Since H. J—— was under the observation of Dr. Shoemaker, his (H. J——'s) wife has given birth to two children, one of which took the prize in a baby show, and H. J—— has apparently completely recovered from his leprosy, and none of his family show it. His wife was of white parentage and had a child by her first husband. The last child of the New England couple is a simpleton. The family have been scrofulous for an unknown period—their ancestors, being of the old New England Puritan stock, for generations had undoubtedly reverted to a condition virgin to syphilis and then two of them, who led lives of gross licentiousness among a race where syphilis manifests its worst ravages, became lepers. These two had not lived together for several years before they became lepers.

And now as to food supply and manners of living. Almost the entire food of the Hawaiian race from time immemorial has been *poi*, which is a paste made from the tubers of the taro plant (*Arum esculentum*). This tuber grows in the water, and is cooked by steaming it among hot rocks covered with earth; then pounded to a paste and allowed to stand until it becomes sour, and this with fish, when they can get them, and sea salt and red pepper, is almost their only diet. Like all other uncivilized races, they are extremely improvident—when food abounds they gorge themselves; when it is scarce, they go hungry. Their houses, until recent years, were simply grass huts, and they lie on the ground—there being no floor—with only some grass and mats made from puhala leaves for beds. Leprosy there, as elsewhere, is largely a disease of the poor and illy provided for portion of the population. With the comforts which have come to them in recent years leprosy is much milder than formerly.

Turn again, for a moment, to the point of the system reverting to a condition virgin to disease.

A few months ago I saw, in consultation with a reputable practitioner of Alameda County, W——, fifty-two years of age, a native of West Virginia, out of which State he had never been until some fourteen years ago, when he came to California. His parents were also natives of Virginia. W—— had never been out of the United States in his life; denied having ever associated with Chinese in any manner. Said that about thirty years ago he had a long continued attack of "sore throat;" his hair fell out at the same time and he had nocturnal rheumatism; denied chancre and bubo. He had been an inmate of the County Hospital for several months some three years ago for an eruption which came out on him. I did not learn what the diagnosis was at that time, but when I saw him in March, 1886, he was a clear case of leprosy.

In February, 1886, I saw J. B——, a leper, driving a dump wagon on Eddy Street, San Francisco. He was thirty-eight years of age; had never been out of the United States, except to come on the railroad from Buffalo to Detroit across the Canadian line (which separates these two cities), and which journey only occupies a few hours. His parents were also natives of the United States, and were healthy, as were also his brothers and sisters. He gave a clear history of syphilis acquired from a squaw in Nevada. He had been under the care of Dr. Huntington at the Railroad Hospital at Sacramento some two years previous for syphilis. This fact I gathered from Dr. Huntington as well as from the patient. His is a far advanced case, and at the present time he is an inmate of our Lazaretto.

But we shall find other and stronger proof of the proposition first laid down, in taking another view of the subject.

The people of Polynesia, including Hawaii, use for intoxicating purposes the root of a plant called ava (*Peper methysticum*). They prepare this by chewing it, and ejecting the chewed root and saliva into a convenient receptacle, when the saliva is strained off and drunk. The chiefs keep one or more servants to do the chewing for them. King Kalakaua, of Hawaii, employed for this purpose, from 1863 to 1878, a period of fifteen years, two lepers, by name Paiaina and Wainee, and King Kalakaua drank the saliva of these two lepers, yet he did not develop the disease. Wainee was under my care from December, 1881, to December, 1884, and was a bad case of the tubercular form of the disease. Queen Kapiolani's first husband was a leper for ten years before his death—which took place in 1859—and she had two children by him during those ten years, but she is not a leper.

I know five white women who have had leprous white husbands; three of these women have each had three children, and the others two children by these leprous husbands, and neither wife nor children have leprosy. Two of these women had been married previously, and, although the children of the first husband in each instance have lived with their leprous step fathers, they have not contracted the disease.

A former Attorney-General of the Hawaiian kingdom, a white man, contracted leprosy there and came to San Francisco a leper, in the early sixties—nearly thirty years ago. While in that condition he became Registrar of the city, being a leper during his entire term of office, and he finally died of the disease. His wife died in the early part of 1891, an aged woman, non-leprous. She lived with him until he died. One daughter has six children, and neither she nor the children are leprous. Another daughter is here now, a highly esteemed young woman—non-leprous. A member of King Kalakaua's late ministry, a white man, has had a leprous mistress residing in his house for many years.

He is not a leper. The former steward of Kakaako Leper Hospital, in Honolulu, married a leprous woman more than eighteen years ago, and lived with her little less than a year, when they separated. Seven years afterward he picked her up on the street one evening and spent the night with her, and, as he expressed himself afterward to me, was disgusted in the morning to find his companion over night was his lawful wife. He had meantime illicit relations with another native woman, by whom he had two children. Neither woman nor children were lepers. Then his wife obligingly procured a divorce from him and he abandoned his mistress and married another leprous woman, by whom he had a child, which died at six months of age with diarrhœa. Then the wife died with leprosy. He then cohabited with another leprous woman, who had a child by him; but before the child was born he married another leprous woman. She died in a short time and he again married, this time to a young woman who is not a leper, and who has several children by him. None of the family are leprous. He is now a Government school-teacher there and Superintendent of a Sunday-school.

I might follow up this recital, but will summarize by saying I know of twenty-six cases where white persons have cohabited with leprous members of the opposite sex for years, openly and knowingly, and not a single instance has occurred of contagion. In addition to this, I have known of five cases among whites where children in the family have had leprosy and the parents have nursed the children for years without contracting it. Instance: In November, 1884, H. W——, a girl about twenty years of age, died here on Bush Street of leprosy. The mother told me she slept with her leprous daughter for six years before the daughter's death. The mother has not developed the disease.

In July, 1882, I was called, in Honolulu, to see a lad, sixteen years of age, who had been a leper for eight years. His father had led a most licentious life; was a lawyer by profession, and his practice consisted largely of divorce cases among natives. He was of missionary parentage—born in the Islands. He denied syphilis, but at forty-two years of age was a sufferer from continuous headache, which culminated in hemiplegia. His oldest child, a daughter, was over eighteen years of age; had never menstruated but three times; could not go to school because of headache, which became unbearable if she kept up any studies. She had a small, weazened face, and there was marked enlargement of the post-cervical and epitrochlear glands. The next child in the family was the leprous son. His left hand and wrist were withered away and were no larger than those of a child of five years. Grasping the arm and holding it up, the hand dropped in either direction as the arm was turned—the boy having no control of it, and from about two inches above the carpal region, hand and arm were analgesic and anæsthetic. To the left of and above the left nipple was an elliptical patch, about two inches by three, surrounded by a raw-ham colored areola about a quarter of an inch wide. Inside of this areola the skin was anæsthetic. A similar patch, but larger, was on the left thigh, and the lad had the same glandular enlargement as his sister. The next child in the family, a girl, had nothing of interest to note only a very decided enlargement of the epitrochlear gland on one side and less of the post-cervical glands. The other child, younger, seemed entirely healthy. No restriction had been placed on the leprous boy; he had used the same towels and bed-linen, and ate at the same table as the rest of the family, but he alone was a leper.

In another case a brother nursed and cared for a sick sister, taking her to Europe to see noted physicians. He spent all the earnings he had saved by years of hard labor—amounting to several thousand dollars—in trying to cure her, but she died in San Francisco a leper and a raving maniac in June, 1887. Her mind gave way under the long-continued suspense. Neither the brother nor the mother, who shared his weary life-work for the last two years, nor any other member of the family show a sign of leprosy.

In another case in San Francisco a devoted sister has been attending and watching a younger brother drag out the weary hours until death shall free him from the long agony. I know them both well. Since the above was written he has gone to Honolulu.

Now, turning to another view of this subject, I have had thirty-five white lepers under observation and only two of them have admitted sexual connection with lepers before they themselves became lepers. The rest, with these exceptions, and these doubtful, denied any, even the most casual, contact with leprosy in any form before the disease appeared in their own persons. But there is other and still stronger proof. In the *Journal of Cutaneous and Venereal Diseases*, January, 1886, will be found these words: "He refers to cases in which lepers have cohabited with their wives during a lengthened period without infecting them, and in which the said wives have even given birth to perfectly healthy children. He cites the experience of a certain physician, who, after several unsuccessful attempts to inoculate himself with tuberculous leprosy, met with the same failure in his experiment upon twenty healthy individuals." These experiments were made in Norway. In a former paper on this subject [1] I gave an account of ten inoculations which had all apparently failed of results, but three years later, or four years in all after the inoculation, one of the subjects, Keanu, a native of Hawaii became a leper. Inquiry into the family history in this case, however, destroys its being received as evidence for or against the doctrine of contagion. Dr. S. B. Swift, Resident Physician at Kalawao Leper Settlement, has recently shown [2] that Keanu belongs to a family of lepers. His first cousin, his own son, and his sister's son were all lepers before Keanu. Commenting on this case, Dr. Swift says: "But supposing that the inoculation did propagate the disease in Keanu, then I would say that its ravages in this case, in the short space of five years, are such as to make it unparalleled in the history of this settlement, and contrary to what little experience I may have acquired during a continuous residence among a thousand lepers for nearly two years." I believe Keanu had the disease in his system before he was inoculated. The Hawaiian race is so thoroughly saturated with it as to make any experiments on them in this direction utterly unreliable.

In the chronicles of the London Missionary Society, March, 1884, is the following by Rev. James Kennedy, M.A.: "Lepers are found in all parts of India, not in such numbers as to be an appreciable portion of the population, but in such numbers as to be well known. They are regarded by the Hindoos as objects of divine displeasure, not on account of wickedness in the present life, but on account of wickedness committed by them in a former birth. While thus regarded they are not excluded from society, as was the case with the Jews, and is still the rule in some parts of the world. They are allowed to move about, and to ask alms of those they meet. At Benares, I have sometimes seen them sitting on a native bedstead with persons who, if they did not touch them, showed at least no dread of their immediate neighborhood. While Kumaun was under native rule lepers were buried alive, their nearest relatives heaping earth on them, but since the establishment of British rule, in 1815, this atrocious custom, as well as other customs equally inhuman, has been suppressed."

Rev. J. H. Bruce, of Satara, India, writes: "I cannot find that there are any government laws whatever on the subject of leprosy. There are certainly no laws of segregation, and lepers are found everywhere in their own homes and villages. There are no restrictions in regard to their marriage—there could hardly be any in this land of infant marriages. In the case of adults, the non-lep-

[1] Pacific Medical and Surgical Journal, October, 1885.
[2] Occidental Medical Times, April, 1890.

rous party would shrink from marrying a leper. When, however, one of the parties became a leper after marriage, there would not always, and perhaps not generally, be a separation of husband and wife. . . . We have had in our house for years a child nurse, who is the widow of a leper. . . . You ask how Vishompunt could preach and visit if he was a leper. The fact of his being a leper was well known, and never in any way concealed, yet he continued his pastoral work until within a week of his death."[1]

In the "Report on Leprosy by the Royal College of Physicians," 1862: "The Committee having carefully considered the replies already received, are of the opinion that the weight and value of the evidence they furnish is very greatly in favor of the non-contagiousness of leprosy. The Committee can only repeat the statement made in their former report to the College, that the replies already received contained no evidence which, in their opinion, justified any measure for the compulsory segregation of lepers."

Acting on this advice, the Duke of Newcastle forthwith issued a circular to the Governors of the Colonies expressing the opinion "that any laws affecting the personal liberty of lepers ought to be repealed, and any action of the executive government in enforcement of them, which is merely authorized and not enjoined by the law, ought to cease."—Aitken: "Hand book of Treatment."

Now notice. In India, under native rule, up to 1815, lepers were buried alive, but still the disease persisted; while under British rule, with no compulsory segregation, we find, at the most, only 1 in 1,500 persons a leper.

W. H. Geddings, M.D.,[2] of Aiken, S. C., says: "Isolated cases of leprosy have been observed in Charleston and its vicinity for many years, the present being the latest of a series of twenty that have been brought to my notice during the last twenty-five years. In none of these cases was the disease hereditary, although in one instance a mother and daughter were affected at the same time. In all of these cases, except the one just mentioned, there was not the slightest evidence of contagion, nor has it ever been deemed necessary to isolate those affected with the disease. When well enough they walked about the streets of the city, attracting but little attention, as the people knew from experience that in this country they run no risk of contracting the disease by coming in contact with those affected with it.

"As isolated cases of leprosy have been observed on the coast of South Carolina for nearly fifty years, without any apparent increase in the number of cases, it may be safely inferred that there is but little danger that the disease will ever become endemic in this section.

"The recent enactment of the national quarantine law forbidding the admission of lepers into this country, and the discussion of the subject of leprosy at the conference of State boards of Health, at Nashville, brings this disease to mind. There is no evidence that leprosy is increasing in this State, and yet there is no law that would allow the isolation of the leper. In the century that the disease has existed in Louisiana no case of contagion is known, and to-day persons so afflicted are living with their families and not subjected to the additional affliction of separation from their friends. These people are liable to travel; and but a short time ago a case of leprosy was discovered in Jackson County, Mississippi, and isolated. He was originally a native of Louisiana. The mortality tables show one or two deaths a year from the disease, a fact that does not indicate an increase in the number of cases. Lepers throughout the State are induced to come to the Charity Hospital for treatment, and many remain there until death."—Correspondence Medical News, June 21, 1890.

"That leprosy in Japan is not in the slightest degree contagious or infectious; that the idea to isolate lepers from other patients does not occur to anybody. In my own wards I have always had lepers between other patients, everybody knowing the nature of the disease, but no one objects to the sleeping in the bed next to theirs. No disinfection is ever used. There is a native doctor in Tokio, in whose family the treatment of leprosy has been carried on as a specialty for at least three generations, he and his whole family live in the same house with his leper patients. For a hundred years, many, many thousands have been treated in that same house in the centre of a capital inhabited by more than a million of people and never one case of contagion has happened."—Letter of Dr. Baelz, Professor of Chemical Medicine at the University of Tokio, to the late Rev. S. C. Damon, of Honolulu.

There are nine Sisters of Charity on Sheldrake Island, in the mouth of the St. Lawrence River, in a lazaretto, living in the same house with a number of lepers, washing the leprous ulcers and caring for them as long as life lasts with the poor creatures. The sisters have been engaged in this task for twenty-one years, and not one has contracted the disease. There are six of these same devoted women engaged in the same duty at Molokai. They have been on duty there and at Kakaako Hospital, Honolulu, since January, 1884, when they went there at the request of the Hawaiian Board of Health, made on my motion and request.

The case of Rev. Father J. Damien is often cited as an instance of contagion. In the latter part of 1882, I told the father, with whom I was intimate, that he had syphilis, and urged him to submit to treatment for the same, but he refused. I first noticed the scars of stellate cracks at the corners of his mouth, then on examination I found he had leucoplakia buccalis. He told me, on inquiry, of his having been for several years a great sufferer with nocturnal pain in his bones; his hair fell out, and he told me of some eruption, of what nature I could not make out from his description, he could only tell me it was a scabby rash, which came out on various parts of his person. There was marked enlargement of both epitrochlear and post-cervical glands. This was two years before the first symptom of leprosy appeared, which began with an anæsthetic patch over one malleolus. When I told him he had syphilis, he asked how that could be, saying he had never had carnal knowledge of a woman in his life.

"In a report given a few days ago by the head physician of Norway, for the cure of leprosy, it is shown that by the end of 1856 there were known in Norway 2,863 cases of leprosy, of whom but 235 were treated in hospitals, and 2,628 in their houses. Since then there had been steadily more isolation, and thereby a steady diminishing of new cases, so that by the end of 1866 there were 2,704 cases, and of these 795 were in hospitals, and 1,909 in their houses; a decrease of 159 cases. By the end of 1876 there were 2,008 cases, showing a decrease of 696 cases. Since, the decrease has been regular; thus there were known, in 1877, 1,923 cases; in 1878, 1,853 cases; in 1880, 1,582 cases, of whom 617 were in hospitals, and 965 in their houses. Thus the decrease of this disease is from 2,863 cases in 1856 to 1,582 in 1880; in all 1,281, or forty-five per cent."—*Hawaiian Gazette*, March 10, 1883.

Summing up this statement it will be seen that, beginning with 1856, we find one case in twelve (or a little over) segregated, and 2,628 different sources of contagion—according to those who believe in contagion—engaged in spreading the disease, and yet the disease began to decrease, so that with a gradually increasing number of cases segregated (or rather varying number, for in 1866 795 were segregated, and in 1880 only 617), in 1880, forty-five

[1] Letter to C. M. Hyde, D.D.: "I find from the censuses of the following provinces of 1871 and 1872, comprising nearly the whole of India, viz., Bengal, Madras, Bombay, the Central Provinces, the Northwest Provinces, Oude, Coorg, and Mysore, that the total number of lepers then enumerated was 99,639—or 1 in 8,864 of the population; but as I have already stated about 1 in 1,500, or 120,000, would be, I believe, nearer the truth."—Leprosy, by W. Munro, M.D., C.M., p. 42, Manchester, 1879.

[2] MEDICAL RECORD, August 19, 1884

per cent. of the disease disappears, but still about three-fifths of the cases are at large. It has been asserted, however, that those who were living in their houses were carefully segregated. Drs. Danielssen and Boeck say: "In Norway most of the cases of leprosy occur among the very poorest classes of the inhabitants, and especially among those living around the shores of the deep bays or fiords on the west coast. The huts of the people generally are of one low narrow room, in which all the family live, with a small window that is not made to open; are usually planted down in a damp site, and surrounded by filth."—College of Physicians' Report, p. lxvii.

Drs. Danielssen and Boeck say that "among the hundreds of lepers whom we have seen daily not a single instance has occurred of the disease spreading by contagion. We know many married persons, one of whom is leprous, cohabiting for years without the other becoming affected. At St. George's Hospital many of the attendants of the inmates have lived there for more than thirty years, and are quite free from any trace of the disease. . . . As the result of our observations, we have only to deny the contagiousness of leprosy."—College of Physicians' Report, pp. 4, xix.

While residing in Honolulu, a Norwegian lady of standing in the community told me that she had frequently, in previous years, visited the leper hospital at Bergen, Norway, and had seen the leprous inmates engaged in making socks, gloves, mittens, and embroidery, which articles were freely used by the community at large.

Now let us bear in mind that so-called segregation began in Norway in 1856, with a little less than one leper in a dozen segregated, and with at no time one-half the cases so disposed of, the disease decreases forty-five per cent. in twenty-five years. Like results follow like causes is an old adage.

Segregation began in 1866 in Hawaii, and since that time has been followed out with a really brutal severity. At no time since the inauguration of the system has the proportion of cases segregated fallen as low as one-half, as far as I could find out, and I had the fullest opportunity to know of any one. The white population there are terribly in earnest, and, as they control the policy of the country, they have exercised every ingenuity in this matter, so that it may be considered certain that an average of two-thirds, at least, have been for the entire period under a restraint much more pronounced than is the case in Norway. Yet there is not the slightest evidence that the disease has decreased, at least I know of no such evidence. From all I hear from there, the proportion of lepers continues as great, if not greater, than it has for years. That the disease does not manifest as severe symptoms as formerly is certain, but I know of no reason to believe the percentage of those afflicted has lessened at all. On the contrary, both the total number and the proportionate number of cases would seem to have steadily increased. Up to April 1, 1884, the total number of lepers consigned to Kalawao Leper Settlement from its institution in 1866 was 2,864. The Report of the President of the Board of Health to the Legislature at its session in the early part of last year shows that: "On March 31, 1888, it was estimated that there were then at large throughout the kingdom 644 lepers. It was only claimed that this estimate was an approximate one. It is found in practice that it is impossible at any time to make an absolutely accurate estimate of those who are not already segregated. During the biennial period ending March 31, 1890, there have been carefully examined by the Examining Board 1,087 persons; of these 726 were pronounced to be lepers, 207 were entered under the head of 'suspects,' and 154 were discharged as unaffected. This number of lepers closely approaches the number supposed to be at large at date of last report. That the number was underestimated is quite evident from the fact that, according to the best information obtainable, there were at date of this report about 100 persons supposed to be affected by the disease still at large, who have not been before the Examining Board."

From the report of Mr. R. W. Myer, Agent of the Board of Health, at the same time, there comes the information that there was at Kalawao then 1,159 lepers segregated. In 1866, when segregation was first made compulsory, the natives submitted willingly, no one thought of hanging back even, as is a well known fact, so we may be certain that pretty nearly all known cases went to the settlement. Of late years so bitter a feeling has grown up among them in opposition to segregation, that in quite a number of instances the lepers and their friends have risen in arms to resist the officers sent to apprehend them.

Bring these three facts together. In India, up to 1815, lepers are buried alive to get rid of them; and still the disease persists. In Norway, the disease is disappearing without segregation, for putting two cases out of five into hospitals, where they are allowed to carry on their handicrafts, and sell the products to those outside cannot be called segregation. In Hawaii, where as thorough segregation as the government, aided by public opinion, can enforce is carried out, the disease steadily increases. And it is to be remembered, in Hawaii, a little country, where everyone knows his neighbor, and anyone with a spot or blemish is looked at with suspicion, it is much harder to conceal a case of leprosy than it is in larger communities, where a person can live much more to himself. The conclusion, to my mind, is irresistible that segregation cuts no figure, one way or the other, in preventing the spread of leprosy.

Let us take another view of our subject. Jarvis[1] says: "Before Captain Cook's visit diseases were few and simple, subsequently they increased in number and violence, while the remedies and knowledge necessary for arresting them remained unknown. . . . The habits of the natives in both respects, are now better than they were before their discovery, when drunkenness, produced by the use of *awa*, and promiscuous intercourse and incest were almost part of their natures. The former, no doubt, destroyed many, and created a disposition to disease in more, but the natives were never so completely addicted to it as to make it a primary cause in their destruction. The diseases incident to the latter have extensively run throughout the whole race, doing irreparable injury in poisoning the very fountains of life, and engendering upon offspring effete constitutions. In 1842 the virus had almost run out, but since, owing to the great influx of shipping from all parts of the globe, it has again developed itself in new and horrible forms with a virulence and fatality unequalled since the days of Cook."

To understand this matter we must go somewhat into the question of sociology.

Before the advent of the whites in Hawaii, marriage, as we understand the word, one male and one female consecrating themselves to each other only, was practically unknown. About the first lesson the Hawaiian mother taught her infant after it could walk was the *hula*, or national dance, which is neither more nor less than the motion of the sexual act. She began by placing one hand on the abdomen, and one on the back, and then instructing her charge to make three motions to the right and forward; then the same left and forward; then three directly forward, the body above the umbilicus being held as near rigid and immovable as possible. The more lascivious the action, the more accomplished the performer. I asked several of the old natives why they taught their children such things. They replied that in the case of girls, if they fell in the way of some chief or rich man, and succeeded in pleasing him, their fortunes were made. They fully believe that a girl cannot have her menstrual flux the first time without, as they express it, "she is opened up," so it is the common custom of the land, when the girl arrives at about the period of puberty, for her to take her first practical lesson of the

[1] Jarvis's History.

hula. Father Damien told me he knew a kahuna (sorcerer) at Kohala, Hawaii, who had a great reputation in such cases, and he, Father Damien, had often seen parents taking their young daughters to this kahuna for this purpose. It is not at all infrequent, however, for the father or the brother to perform the operation for the young lady's benefit.

Somewhat later in life, in former times, a kahuna took a class of girls, and, after making an offering to Laka, the Hawaiian Venus, took one of the class and went through the performance with her, while the rest looked on and made mental notes of how to do the act in the most artistic and satisfactory way.

Friends in visiting each other exchanged wives over night, and strangers were accommodated with women as a matter of common courtesy.

I once asked Queen Kapiolani what proportion of native women, in her opinion, had never had carnal knowledge of any other man than their lawful husbands. She replied, "Aole akahi wahine likapu ke la" (not one woman like that). There is no word meaning chastity in the language.

Now, as we have seen, when syphilis was first introduced by Captain Cook in Hawaii, "one-half the population died, leaving the dead unburied for want of those able to perform the rites of sepulture." But this does not tell us the result in individual instances. Let us see what happens in such cases. While we cannot see it as it was at first, still enough yet exists to give us some insight into the case.

Charles C——, a half-caste, came to the Government Dispensary, in Honolulu, in 1882, with his foot and the leg half-way to the knee gone. A raw conical stump remained, some four or five inches long, presenting a granulating surface, bleeding easily, and which had continued in the same condition for many months. He was a man of about thirty-three years of age, a carriage-driver, in fair circumstances. I could get very little history of the case, simply that gangrene had come on without appreciable cause or reason, and had left the parts in the condition they then were. As he gave a syphilitic history, I applied mercurial ointment to the stump, and gave him iodide of potassium internally; as a result the stump healed as if by magic. Some months afterward he came again with some masses projecting from the anus, which I diagnosed as hæmorrhoids and ligated; but when the ligatures came away I found raw ulcerating surfaces remaining, which would not heal until I put him on antisyphilitic treatment. Again some months passed, when he came with a slight cough and complaining of great pain over both sides of the thorax. The lungs were consolidated in patches; hectic fever set in, and in a few weeks he died. The last time his friends persuaded him that he had a "native sickness," and only a kahuna could cure him, and so he would not submit to treatment. According to native ideas, some diseases are foreign and require a doctor, some are native and require a kahuna, or sorcerer.

Kealoha, a native woman, about twenty-five years of age, came to the dispensary with the thumb and all the fingers of the right hand gone. From just above the wrist-joint, and involving the entire stump that was left, was a raw sore, and that stump was bent around to a right angle with the fore-arm. I could get no history of the case, but, taught by experience, I dressed the stump with mercurial ointment and gave her iodide of potassium internally, with the result of sudden improvement and a complete cure in a few weeks. If such cases occur in this country, I have never seen them. I saw, in several cases, deep cracks form opposite the elbow, shoulder, and wrist joints, and there was every prospect that similar results would follow, but the patients died before the process was completed.

The native pastor of one of the churches in Honolulu told me that he, his father, and six brothers all led very licentious lives. His father and brothers all died, as he affirmed to me, with syphilis. The pastor himself was converted, but not soon enough. His shin-bones became badly marked with syphilis. His wife was also a great sufferer with it. His eldest daughter, at about thirteen years of age, broke out with large rupial scabs on her face, and became so anæmic that she looked like a corpse. Iodine, mercury, and arsenic, pushed to extremity, brought her around for a time, but just as soon as the remedies were stopped she would get a relapse. Finally, the disease got the mastery, and she became a leper. The time came when the remedies seemed to lose effect, and no amount her system would bear stopped the progress of the disease. I have seen many, many similar cases, and I cannot help believing that leprosy is a result of syphilis.

Previous to the advent of the whites in Hawaii the natives went naked, and their labor consisted in cultivating enough land to insure them poi, or sweet potatoes (and that, in very productive soil, was not severe), in fishing in waters teeming with fish, and in an occasional intertribal war. Their weapons consisted of wooden spears and clubs, they having no knowledge even of the bow and arrow for war purposes, so that their fighting merely served to keep down redundant population. With the advent of the white races, however, a new order of things began. An immense demand for sandal-wood—with which the islands abounded—for export to China commenced, and the chiefs forced the people to cut and carry this wood in great quantities to ships in waiting, they receiving in exchange all the, to them new and varied, products of civilization. As the islands had no beasts of burden, man himself had to transport on his back the wood cut in the mountains, and thus brought it to the sea. Not only this, but the advent of the missionaries added immensely to their burdens. Shortly after the preaching of the gospel began, the Queen regnant and many of the leading chiefs became converts to the new faith, and churches and school-houses had to be built. Many of these buildings still remain—large stone structures, going to decay—while the people for whose use they were intended, and whose labor built them, are all dead, and there is no one left to use them. Money for the use of teachers and preachers had to be raised, and thus their burdens became heavier on every hand. Added to all this, new ideas came in to exclude the beliefs of centuries. The Hawaiian has always looked to his chief to do his thinking to a large extent for him. The early missionaries almost at once succeeded in making converts of the rulers of the land, and, through them, became the real governing power of the nation.

New England Puritanism, rigid and severe, was, as far as could be, substituted in the place of heathenism and gross, almost boundless, sensualism and licentiousness. It was sought to change the habits, manners, and customs of centuries in a single generation, in fact at once, from savagery—with all its license for the exercise of human passions—to the rightful and steady religious and moral life which the Christian faith demands of its true believers and followers.

Converts to the new religion became so numerous that on one occasion it is related that a missionary seated the multitudes on the grass and went among them with whisk broom in one hand and a basin of water in the other, and, sprinkling the fluid over the crowd with the broom, baptized three thousand of them in a single day. Laws against licentiousness were passed, and executed, as far as possible, with the greatest severity. Education, too, was enforced, and the unlettered savage was sedulously taught to read and write, and encouraged to study the Scriptures and fit himself for a life beyond this world. In fact, what the poor native had all his life been taught to believe by his heathen priests was to be thrown overboard, and what his new teachers taught him at once substituted instead. What was right one day was wrong the next. What must be done to insure safety and happiness one day was wrong the next day, and was certain to damn a man if persevered in. New wants, also, made

themselves known. The women wanted bright-colored calicoes to array themselves in, and mirrors to admire their counterfeit presentment in afterward. The men wanted guns and ammunition to fight with; and both sexes a multitude of things too numerous to mention, which civilization was bringing them. Under all this stimulus, so suddenly coming on, there could only be one result—their nervous systems gave way and the neurotic condition, which I have before insisted on as a precedent of leprosy, was induced generally among them, so that, while in other lands and under different conditions syphilis rarely develops into the form commonly known as leprosy, it here became a widespreading epidemic affecting, it has been computed, from four to five per cent. of the population.

And now let us sum up our study.

1st. We have the clearest and most unmistakable proof that leprosy is a non-communicable disease, as leprosy, under any circumstance. Cohabitation for many years, inoculation, and drinking the saliva of lepers, have failed in any and every instance to communicate it, and segregation plays no part in preventing the spread of, and non-segregation in spreading, the disease.

2d. Leprosy invariably follows the introduction of syphilis among virgin races so quickly as to point most strongly to a common origin. We find this exemplified in the case mentioned by Mr. Sturges, where, in the short space of fifteen years, a large number of the inhabitants of an isolated community became lepers, and where there is no evidence that they ever were in communication with a leper—for it is not a supposable case that crews of merchantmen would have cases of leprosy among them, it being a disease which, in a short time, would surely incapacitate a man for the active duties of a sailor's life, even if the disease were communicable, which I cannot believe it to be.

3d. It is a well-known fact that syphilis, in an immense majority of cases, cannot be acquired under any circumstance a second time. While the twenty cases in which I inoculated syphilis on lepers are not absolutely conclusive, still it is a point worth consideration. The Hawaiian race are so much under the influence of syphilis that no absolutely reliable data can be drawn from experiments in this line with them. It is to be hoped that this experiment should be tried by competent observers under more favorable circumstances. We all know that syphilis is eminently contagious in its primary condition—absolutely non contagious in its late manifestations. This being the case, would it not follow as a law that the nearer the initial lesion—the chancre—the more active the virus?

4th. By accepting the view I have put forth, we have an easy, natural solution of leprosy—a non-communicable disease after it declares itself as leprosy—spreading as it does spread, and still being in itself non-contagious and non-communicable. In this way, also, we are able to account for those isolated cases of leprosy which now and again appear in communities otherwise free from the disease, and in which the subjects affected with it can never by any possibility have come in contact with it.

In closing this paper, I wish to put one more observation on record, to be worked out, perhaps, in the future. Without going into particulars and statistics to prove the assertion, it would appear to be the case in Hawaii that members of the German race are far more subject to leprosy than those of the British or American. As far as I could compute, their tendency to acquire the disease is four times as great. This estimate, and it is only an estimate, being reckoned on the number of cases in proportion to the total number of each of the above races who are inhabitants of the kingdom. Can it be because the British and American are of mixed race and parentage and the German of unmixed only? If we look over the world we shall find leprosy most prevalent, and continuing its ravages longest, in countries whose inhabitants are of unmixed parentage, China, Japan, India, Norway, and Hawaii are instances.

32 O'Farrell Street, San Francisco, Cal.

OBSERVATIONS ON THE HYPODERMIC USE OF GOLD AND MANGANESE IN TUBERCULOSIS—REPORT OF CASES OF RECOVERY.[1]

By JOHN BLAKE WHITE, M.D.,
PHYSICIAN TO CITY HOSPITAL, ETC.

Attention to the therapeutic value of chloride of gold and sodium, combined with iodide of manganese, when administered hypodermically, was directed by me in two theses upon this subject, published in the Medical Record, December 27, 1890, and March 21, 1891, respectively.

Investigations had been made and observations of the results carefully noted for some time before my impressions of the value of this treatment were published. It was found, when these salts were administered internally, that a lesser appreciable effect was produced than when given hypodermically, and the reason for this difference may be found in the remark made by Bartholow, that the salts of gold are singularly apt to undergo decomposition in the alimentary canal. But there is another reason, quite as important to note, for the difference in effect of the gold remedies when introduced into the system by the stomach and hypodermically. The glandular system is especially prone to tubercular degeneration, and the absorbent system is therefore slow to take up and assimilate any remedy taken into the stomach; but when introduced under the skin, however, it enters the blood immediately in a pure chemical state, and is rapidly diffused throughout the body.

The first evidences of tubercular invasion presented to us are an altered condition of the blood, with symptoms referable to disturbance of the organs of digestion, and are manifested by absorption of adipose tissue and progressive muscular atrophy. A low degree of vitality supervenes, and respiratory vigor is so diminished that accumulation of mucus in the air-cells and bronchi is permitted, producing in time inflammation, which, with its accompanying conditions, establishes a nidus for the generation of inimical bacilli.

Let us bear in mind that the conditions giving rise to phthisis are numerous and diverse. The action of these conditions, when traced in the individual, may be divided into twofold causes, described as general and local. In the first, the individual constitution and the functions of nutrition and assimilation become primarily involved, as already stated. Among the latter, or local causes, we find the primary seat of the disease to be in the organs of respiration. Certain changes in the epithelium and pulmonary parenchyma lead to retrograde products, through which the lymphatic and vascular systems, and finally the constitution generally, become infected.

Among the most important general causes affecting the whole system may be mentioned family predisposition, syphilis, fevers, intemperance, insufficient food, deficient ventilation, influences of climate, damp soil, etc. Of the local causes, inflammatory affections of the lung and pleura, certain occupations, and chest injuries are the most prominent. *Thus it will be seen that the tubercular process takes its inevitable rise in physical debility and blood deterioration.*

The relation which pleurisy bears to tubercle has been pretty generally recognized. Anstie, in a pointed paragraph, asserts "that of the sequelæ of pleurisy, one outweighs all others in interest, viz., tuberculosis." It is now well established that not only pleurisy often occurs in phthisical lung disease, but also that pleurisy itself is capable of originating tubercle even in previously healthy persons. No one has more forcibly presented this fact than Dr. J. R. Leaming, whose researches and writings on this subject warrant profound commendation.

Westbrook, of Brooklyn, among others, has also laid great stress on the pleuritic origin of tuberculosis.

The greater or less amount of adhesions of the op-

[1] Read before the New York County Medical Association, June 20, 1892.

posed pleural surfaces which follow inflammatory affections of this membrane are exceedingly prone to become permanent, acting as a constant menace to the lung, exciting irritable cough, resulting in a material lessening of lung capacity, and ultimately in the destroying of lung integrity. I do not believe that a pronounced pleuritis will subside without leaving obscure lesions, which months, and in some instances years, of skilful and persistent treatment can alone remove. An alterative course of treatment, with frictions of the chest and regular lung exercise, will go far toward removing lesions which, if neglected, would result in much subsequent impairment.

The deposition of tubercle is essentially a process arising from blood impoverishment following faulty nutrition. Cases of tuberculosis for years have been successfully treated by judicious hygienic and medicinal measures. The observations of Dr. Bennett, of Edinburgh, confirmed by many others, tend to prove that treatment simply aimed to correct mal-assimilation of food not infrequently arrests the tubercular process and causes the complete disappearance of all general symptoms, as well as physical signs of tubercular degeneration ; hence it should manifestly be our aim to stimulate the flagging nutritive functions, and thus promote assimilation of food rich in elements which are deficient in the circulating current.

Holland, in adverting to this disease, uses this language : " That it must be fairly admitted that the progress of medical science has effected nothing toward a valid cure, though it is less an opprobrium upon medicine than at first thought it might appear. The more distinct knowledge that has been acquired of the tubercular diathesis, of the tendency manifested by certain habits and in particular textures to the deposits of the peculiar morbid matter, and of the more especial direction to the lungs, which elicited Louis's assertion that after fifteen years of age tubercles were never found in any part without being also present in the lungs, all directly point to a specific constitutional disease for which none other than a specific antidote is likely to be of complete or certain avail."

If we have, as my experience leads me strongly to believe, antidotal remedies in the preparations of gold and manganese, we are approaching that much-desired stage in the therapeusis of tuberculosis when we can look with greater certainty to masterful aid from medicine in combating this dread destroyer of human life.

In the incipient stage of pulmonary tuberculosis I have frequently seen the injections of the gold and manganese promptly reduce fever, diminish the cough and expectoration, check colliquative sweats, improve the appetite, restore physical vigor, and increase the body weight. In the majority of cases all these effects follow in rapid succession, *pari passu*, with each injection. Had I not frequently seen the results described follow this treatment, I would feel much more hesitancy than I do in proclaiming the value of this method.

Corroboration of the statements I have just made are constantly reaching me from medical men in various parts of the country, who have paid me the honor to test it. To Dr. O. H. Merril, of Corinna, Me., I am indebted for favoring me with the result of a large experience during the past year, and especially for his frank and generous expression of confidence in the treatment advised by me.

Dr. Merril[1] writes : "Sufficient experience has now been had to enable me to form at least a provisional opinion as to the value of your method of treating tuberculosis. Ten cases have been treated for a period of time long enough to show what the remedy can do. Other cases have received only a few injections, and will not be mentioned here. All the cases were at the same time given such other treatment as seemed appropriate. Special diet, proper hygiene, and creosote were ordered in all cases. In addition, four of the patients had cod-liver oil. In attempting to form a correct opinion of the value of the injections, I rely chiefly on the improvement obtained under the combined treatment, as compared with the results observed in previous years with an entirely similar series of cases. In the case of a woman, thirty-two years of age, with extensive disease of one lung, of eighteen months' standing, the injections were suspended for a fortnight ; at the end of that time her condition was much worse, and she begged to have them used again. She now rapidly improved once more ; and I am almost, but not quite, certain that they had the good effect which she attributed to them. One case was apparently cured, but as active treatment of other sorts was used, the part played by the injections in bringing about the result cannot be definitely stated. One case has received fifty-eight injections, and one case only ten ; nearly all of the rest had between thirty and forty.

" All of the ten cases have greatly improved in every respect, several of them to such an extent that they declare themselves well and refuse further treatment. That they are not well is shown, in the case of nine, of them, by an evening temperature of 99½° F., a pulse of 85 to 95, a slight cough, and the occasional presence of a few bacilli in the sputum. My impression is, that notwithstanding their present good condition most of them will probably relapse, for the reason that they have not sufficient intelligence to persist in systematic treatment, and for the further reason that they have not sufficient money to obtain the benefit of suitable climatic influences.

" I must say, however, that I have never before seen such rapid and uniform improvement in my cases, and, although I am extremely sceptical in regard to therapeutics, I am forced to admit that, after all the deductions which strict logic requires have been made, the injections have probably considerable power to ameliorate the condition of phthisical patients. In fact, I have in some cases been surprised at the results. It seems to me that we have here no specific, but a remedy capable of doing good service when used carefully in connection with other treatment, thus constituting a distinct advance in the therapeutics of tuberculosis. I am anxious to see reports from other observers, and especially to see anything which you may hereafter publish.

" The comparison which I have made is very favorable to the new treatment. An improvement that required six or eight months to bring about in former years, has been obtained this year in as many weeks ; symptoms that were formerly very obstinate, have this year yielded quickly. One of the most gratifying effects of the remedy was seen in the increased appetite that sometimes manifested itself within a week, nearly always in two weeks."

I ask your particular attention to the remarkable degree of abeyance in the progress of the disease noted by Dr. Merril in the presence of this potent combination.

I desire here also to record the favorable testimony of Dr. Sylvester, of Portland, Me., who has exploited the treatment with like success. To Dr. Tyndale, also, am I indebted for alluding to this treatment in a most interesting paper read before this Association last meeting.

Dr. James R. Leaming, in adverting to this method of treating tuberculosis, writes, " That the direct treatment in hospitals, instead of giving the patients quinine and cod-liver oil and sending them away to health-resorts to die, is a movement in the right direction. I am glad that you have demonstrated that the injections of the salts of gold in combination act well. I have been satisfied, you know, that the natural method of expanding the lungs, and the use of medicines to promote the absorption of plastic exudates, is a certain method of treatment. But we need all the helps we can get, and I welcome your method as one superior to Koch's and

[1] Medical News, January 30, 1892. Also personal communication received September 24, 1891.

next to the natural one, and I thank you for demonstrating it to the profession."

The salts of gold not only dissipate plastic exudation, but they exert a profound effect upon the functions of organic life, arousing the organs to healthy action and necessarily improving the nutrition.

The precise mode of action of the preparations of gold is not fully determined, but there is good reason to believe that they exert a remarkable influence upon the general nutrition. They appear to manifest their peculiar virtue first upon the circulation, secondly upon the organs of respiration.

It is a recognized fact that certain medicines do expend their special effects on particular organs, as ipecac upon the stomach, strychnia upon the spine, and digitalis upon the heart; but why or how they do so remains, even to us, who employ them so extensively, unsolved enigmas. The classic experiments of Orfila with the chloride of gold upon dogs show that in large doses death resulted from vomiting and suffocation, preceded by paroxysmal cough. T. Lauder Brunton also found that while small doses encouraged the appetite, large doses produced irritation of the gastro-intestinal track with a pseudo-catarrhal condition of the respiratory passages, resulting in death by asphyxia.

Aronowitsch, conducting his experiments on cold-blooded animals, noted that chloride of gold and sodium caused central paralysis, the respiratory function being affected before the heart or brain.

In warm-blooded animals long-continued small doses caused them to maintain a good physical condition and gain in weight; when the dose was increased the pulse became accelerated, the respiration excited, and animal heat was decreased.

All authorities concur, however, in stating that when administered in strictly therapeutic doses the gold preparations exhibit rare eutrophic virtues. Some individuals manifest an idiosyncrasy against tolerance of the salts of gold, in whom most powerful effects follow the minimum doses. I have seen the temperature increased by an ordinary dose to 103° F. and 104° F., and in some instances fall below the normal grade, with chill, which should only enhance a caution in their administration.

As an anti-anæmic, manganese is pre-eminently indicated in tuberculosis. It is an element ever present in the blood as well as in the other fluids and solids of the human body, and is certainly better tolerated than iron in those subject to tuberculosis.

Authorities are not wanting in praise of this salt, especially for its anti-anæmic effects in the cachexia of tubercular subjects. Combined with the chloride of gold and sodium, manganese is especially advantageous in controlling the blood deterioration which so rapidly and perniciously progresses in those subject to phthisis.

The administration of these combined salts hypodermically seems to singularly secure in the organism the very action which Garrod hoped to achieve by the salts of potash, viz., "A ready metamorphosis of the less vital tissues, less vital deposits, less vital plasma, and, of course, of the deposition forming the glandular and other swellings of scrofula."

In my own experience the effects obtained have been first exhilarant, followed by an increase in animal heat and vital activity, the pulse becomes more full and active, and the respirations deeper and less labored. In aggravated cases of lung disease the temperature is invariably elevated, and a decided period of reaction is established. I have noted in some cases a constriction complained of about the chest, amounting in rare instances to absolute dyspnœa. Sooner or later thereafter follows a period of depression, more or less expressed, which, however, is not of long duration. This is generally succeeded by permanent and invigorating effects, manifested by remarkable increase in appetite and body weight, with marked amelioration of morbid symptoms.

My practice is usually to begin with two drops of a carefully prepared fluid representing about one twenty-fifth of a grain of the combined salts of gold and manganese, administered with a few minims of a one per cent. solution of carbolic acid. The injections are best made in the dorso-lumbar region, where the cellular tissue is abundant and where there is greater latitude for absorption.

The following cases will afford examples of the value of the method of treatment I have proposed, but it is not intended they shall convey a claim that the remedies used are specifics in the strict sense of the term. That the treatment effects a greater amount of good in a shorter space of time than any other method of treatment heretofore advocated, clinical results will conclusively demonstrate.

Case I.—Miss S——, aged twenty-one, native born, presented for treatment January 11, 1891. Father, brother, and sister died of pulmonary tuberculosis. A year ago she began to cough and expectorate, throat felt sore, and voice became hoarse. Felt much annoyance from irritation and tickling in the pharynx and larynx, which kept up a constant cough. Examination of the larynx revealed an œdematous condition of the vocal cords and the adjacent mucous layer about the glottis.

The percussion note was dull over the anterior portion of the right lung, and the respiration was harsh and bronchial, with some dry and moist coarse and fine râles. Body weight, 120 pounds.

January 11th, 3 P.M.—Temperature, 99° F.; dose, 1 drop.

January 15th.—Temperature, 99.4° F; dose, 1 drop. Patient felt feverish after last injection, and had slight headache. Cough increased, with bloody expectoration. Throat better, and appetite increased.

January 18th.—Temperature, 98.5° F.; dose, 1 drop. Twenty-four hours after the last injection cough was increased, with bloody expectoration. This day, cough much less; appetite increased; much less throat irritation.

January 20th, M.—No more bloody sputa. General improvement reached. Temperature, 100° F.; pulse, 84; injected 1 drop; weight, 121½ pounds.

January 23d, 6 P.M.—Cough less. Temperature, 98.5° F.; pulse, 80; injected 2 drops.

January 29th, P.M.—Cough decidedly diminished, and little expectoration. Catamenia recurred at this time, and the flow was increased. Temperature, 98.8° F.; pulse, 94; injected 2 drops.

February 1st, P.M.—Feels much stronger, and in every respect better. Temperature, 99.4° F.; pulse, 100; injected 2 drops.

February 5th, P.M.—Temperature, 98.5° F.; pulse, 84; injected 2 drops.

February 8th, P.M.—Temperature, 98.5° F.; pulse, 80; injected 2 drops.

February 15th, P.M.—Temperature, 98.5° F.; pulse, 72; injected 2 drops; weight, 122 pounds.

February 17th, P.M.—Temperature, 99.2° F.; pulse, 82; injected 2 drops.

February 22d, P.M.—Temperature, 98.5° F.; pulse, 88; injected 2 drops.

February 27th, P.M.—Temperature, 98.5° F.; pulse, 80; injected 1 drop.

March 2d, P.M.—Temperature, 98.5° F.; pulse, 78; injected 1 drop.

No other medication received. Though no bacilli were discovered in the sputum, I am quite satisfied that the case was one of undoubted tuberculosis in its early stage. The injections were administered five times in March and April, at intervals of three or four days, and finally once a week during May. At the end of that time the patient was in good condition, and entirely free from all cough and throat irritation. When seen recently was in excellent physical condition, having no cough or expectoration, and weighed 122½ pounds.

Case II.—Mr. J. F——, aged twenty-three years; single; collector. Father and brother died of pulmonary tuberculosis. Up to two years ago was perfectly well. At this time took cold and began to cough and expectorate, and, with loss of appetite, emaciated rapidly. Indications of tubercular invasion were manifest in both lungs, but the right apex was especially affected. On auscultation loud mucous râles were heard, anteriorly, in infra-clavicular region, with a few moist râles extending down to base of chest, and pleuritic friction-sound about the subaxillary and posterior aspects of right chest. Under appropriate treatment—inhalations, tonics, etc.—an improvement resulted, but more or less cough with slight expectoration continued.

February 1, 1891.—The cough becoming more aggravated, the resulting increase of expectoration and losing of appetite and flesh induced him to consult me again. He has been coughing and expectorating muco-purulent sputa for past six months. Sputum was examined by Dr. Charles Lewis Allen, and found to contain bacilli of tuberculosis, the presence of which he kindly permitted me to verify.

Physical Examination.—Right lung: Diminished expansion, dulness of percussion anteriorly and posteriorly at apex, extending down to middle lobe. Modified percussion note over lower lobe anteriorly, but dull posteriorly. Moist râles discerned anteriorly, upper portion of lung, louder mucous râles extending down to base, with increased fremitus. Posteriorly fremitus increased all over the right lung, and some moist and dry râles discerned. Left lung: Percussion sound modified slightly; broncho-respiratory murmur feeble anteriorly and posteriorly. Some loose râles heard over middle portion of chest. Has some irritation in throat, and a feeling of tightness across chest. Body weight, 135 pounds.

Injections were administered about every three days, commencing with one drop and increased to three drops, when two and three drops were alternately given up to June 13, 1891. His general condition remarkably improved, and his body weight increased to 137½ pounds. When seen March 31, 1892, his body weight was 147 pounds. He had no cough, and appeared in every respect a physically sound man.

Case III.—Miss P——, aged twenty-one, consulted me June, 1890, and gave the following history: Mother and brother died of pulmonary phthisis, and father, though living, is affected with the same disease. For the past two weeks she has been suffering from fever and a cough. Before examination some fine moist râles were heard upon the left side, extending from the base of the lung to the apex, more pronounced posteriorly. Under appropriate treatment recovery resulted.

A year subsequently the patient again consulted me, complaining of debility and cough with bloody expectoration; also spat up blood about four or six weeks previously. No appetite, and losing flesh. A specimen of the sputum, which was characteristic, was microscopically examined by Dr. Charles Lewis Allen, who reported the presence of a number of bacilli of tuberculosis, which he afforded me an opportunity to confirm.

June 23d.—A careful examination was made again of the patient's chest. Right side: Dulness on percussion in the infra-clavicular space and at the base, both anteriorly and posteriorly. Harsh respiration was discerned at the upper and anterior portion of the lung, with loud, moist crepitation also heard in the sub-scapular region, becoming finer toward the base of the lung. Left side: Apicial dulness. Loud, moist crepitation in the sub-clavicular region of the lung, with some fine râles heard toward the base. Fremitus increased. Body weight, 111 pounds. Special treatment was commenced June 23, 1891. All the temperature tests were made between three and four o'clock P.M.

June 23d.—Temperature, 100.5° F.; dose, 1 drop.
June 25th.—Temperature, 101° F.; dose, 2 drops.
June 29th.—Temperature, 101.2° F.; dose, 2 drops.
July 2d.—Temperature, 99.8° F.; dose, 2 drops.
July 7th.—Temperature, 101° F.; dose, 2 drops.
July 10th.—Temperature, 99.6° F.; dose, 2 drops.
July 13th.—Temperature, 100.4° F.; dose, 2 drops.
July 16th.—Temperature, 99° F.; dose, 2 drops.
July 20th.—Temperature, 99.6° F.; dose, 2 drops; weight, 109 pounds.
July 23d.—Temperature, 100.2° F.; dose, 2 drops.
July 29th.—Temperature, 99.6° F.; dose, 2 drops.
July 31st.—Temperature, 100.2° F.; dose, 2 drops.
August 3d.—Temperature, 100.2° F.; dose, 2 drops.
August 7th.—Temperature, 100.2° F.; dose, 2 drops.
August 10th.—Temperature, 100.4° F.; dose, 2 drops.
August 13th.—Temperature, 100.4° F.; dose, 3 drops.
August 17th.—Temperature, 99.4° F.; dose 3 drops.
August 20th.—Temperature, 99.4° F.; dose, 3 drops; weight, 112 pounds.
August 25th.—Temperature, 99.2° F.; dose, 2 drops.
September 3d.—Temperature, 99.6° F.; dose, 2 drops.
September 10th.—Temperature, 99.8° F.; dose, 2 drops; weight, 113 pounds.
September 17th.—Temperature, 99.4° F.; dose, 2 drops.
September 26th.—Temperature, 99.5° F.; dose, 2 drops.
September 30th.—Temperature, 99.2° F.; dose, 2 drops.
October 3d.—Temperature, 98.7° F.; dose, 2 drops.
October 8th.—Temperature, 99° F.; dose, 2 drops.

At this time the patient was much improved and left the city. While away she was quite ill with a severe cold, under the care of Dr. T. A. Pease, of Norwood, N. Y., who wrote me of her condition. Under his care she finally improved sufficiently to return home, and special treatment was resumed December 28th.—Temperature, 99° F.; dose, 1 drop; weight, 112 pounds.

January 3, 1892.—Temperature, 99.2° F.; dose, 1 drop.
January 8th.—Temperature, 99° F.; dose, 2 drops; weight, 112 pounds.
January 16th.—Temperature, 98.5° F.; dose, 3 drops.
January 23d.—Temperature, 99.5° F.; dose, 3 drops.
January 30th.—Temperature, 98.8° F.; dose, 3 drops.
February 6th.—Temperature, 98.8° F.; dose, 2 drops; weight, 118½ pounds.
February 13th.—Temperature, 98.5° F.; dose, 2 drops.
February 29th.—Temperature, 98.5° F.; dose, 2 drops.

The only other treatment which this patient received under my care was a mixture containing the hypophosphites and Clermont's syrup of the soluble arsenite of iron.

The patient is at present free from cough and expectoration, and wearing the general appearance of health. Was seen May 31, 1892, at which time she appeared perfectly well and weighed 121½ pounds.

Case IV.—Miss H——, native born, nineteen years of age, consulted me April 15, 1891, and gave the following history: Father and maternal aunt died of phthisis. Mother has had several attacks of hæmoptysis, but is still living. Two months previous to date named she took cold and felt pain on the left side of chest, about the second and third intercostal spaces, extending through to the subscapular region posteriorly. Has a very troublesome cough, which especially disturbs her at night and in the morning. Expectorates much muco-purulent matter which was examined by Dr. Charles L. Allen, and found to contain a large number of tubercle bacilli. Sweats every night. Appetite, poor; emaciation, marked; body weight, 117 pounds; temperature, 101.5° F.

Left chest showed diminished expansion with dulness on percussion in infra-clavicular region, increased dulness extending downward. There was infra-clavicular flattening, and auscultation revealed harsh bronchial breathing,

with loud moist crepitation. Lower down there were some fine dry and moist râles. These latter sounds were heard both anteriorly and posteriorly. Fremitus increased on left side.

On right side the percussion note was modified, and moist crepitation with increased fremitus were noted in the upper and middle portions of the lung. The first hypodermic was given April 20, 1891. Temperature, 103.5° F.; dose, 1 drop.

April 23d.—Temperature, 102.2° F.; dose, 2 drops.

April 27th.—Temperature, 104° F.; dose, 3 drops.

May 1st.—Temperature, 100.8° F.; dose, 3 drops.

May 9th.—Temperature, 100.4° F.; dose, 3 drops; night-sweats and cough ameliorated.

May 14th.—Temperature, 102.5° F.; dose, 3 drops.

May 17th.—Temperature, 100.8° F.; dose, 3 drops.

May 22d.—Temperature, 101.8° F.; dose, 3 drops.

June 10th.—Temperature, 99 8° F.; dose, 3 drops. Has no night-sweats, and menstruation, which has been suppressed, was restored. Upon examination of the chest the respiration was clearer; cough and expectoration less. Sleeps well at night; looks better; weight, 120 pounds.

July 27th.—Temperature, 102.8° F.; dose, 3 drops.

August 3d.—Temperature, 101.4° F.; dose, 3 drops.

August 10th.—Temperature, 100.4° F.; dose, 3 drops.

August 17th.—Temperature, 102.4° F.; dose, 3 drops.

August 24th.—Temperature, 102° F.; dose, 3 drops.

September 7th.—Temperature, 101° F.; dose, 3 drops.

September 14th.—Temperature, 101.5° F.; dose, 3 drops.

October 1st.—Temperature, 101.4° F.; dose, 3 drops.

At this time the patient was so much better that she married and left my charge for two months, returning for treatment the latter part of December, with return of her symptoms.

December 21st.—Temperature, 102° F.; dose, 3 drops.

December 27th.—Temperature, 98.5° F.; dose, 3 drops.

During January and February she became so debilitated that she could not visit the city for treatment, and the injections were continued by Dr. C. L. Allen once a week at her home. During much of this time she was confined to her bed, and when visited on one occasion by me, I left her with little expectation of seeing her out again. Dr. Allen, however, visited the case and administered the injections regularly up to April, after which time she rapidly improved in health. A letter of recent date from her husband informed me that she is continuing to improve rapidly—goes out walking every day, has been to the city on shopping expeditions without feeling fatigued, and in every way shows that she is stronger and better than she was last autumn. She seldom coughs and expectorates little. Continuing, he says that she eats and sleeps well, and looks fifty per cent. better than she did three months ago.

This was one of the most unpromising cases, and the result of treatment has been as unexpected as it is gratifying.

Besides the gold and manganese injections the patient received from time to time only such medication as the urgency of the symptoms required, such as remedies to allay cough, cardiac stimulants to alleviate asthenia, etc. Whatever eutrophic effect has been produced must alone be attributed to the hypodermic use of the gold and manganese fluid.

Case V.—Mr. D——, native born, aged twenty-eight, married, consulted me August 3, 1891. Mother and brother died of phthisis. November, 1888, had a cough followed by hæmoptysis. Cough continued more or less up to August, 1889, when it again became more severe, and again he had hæmoptysis. In July, 1890, he was again troubled with coughing, and at this time felt pain in the chest followed by hæmoptysis. After this the cough lessened and he felt better till August 1, 1891, when the same pain in the chest returned, with cough and hæmoptysis in an aggravated degree. He then began to lose appetite, feel weak, and expectorate. Upon examination, dulness was discovered over right apex, and percussion was not clear over the left. In the right region respiration was bronchial, and moist râles were plainly heard. There were pleuritic adhesions at the base of the right lung, and the respiratory murmur was feeble over the lower lobe. The patient was put upon the peroxide of hydrogen internally, with gold and manganese injection. The first injection was given August 3, 1891.

August 4th.—He had a pretty severe hemorrhage.

September 4th.—Body weight was 128 pounds, appetite improved, and cough ameliorated.

The last injection was given November 20th, at which time he weighed 133½ pounds. His appetite had returned. He had no cough and felt fully restored. The patient, when seen a few weeks ago, was in good physical condition, and said he had no cough and felt stronger and better than he had for a long time.

I have other cases equally as interesting, but will not take up more of your time with these statistics, for the cases quoted will suffice to show in a general way the practical bearing and value of the method of treatment under discussion.

There is a growing necessity arising for the establishment of a sanatorium, near the city of New York, for the reception and special treatment of the particular class of cases above referred to, which must sooner or later take form and express itself in the founding of an institution on such a scale as to be within the reach of others than the wealthy. Such an institution is now in process of erection at Brentwood, Long Island, the location being especially adapted by its soil, environment, and all important requirements.

I point with a feeling of just pride to the superb generosity of our profession! What other class of men than physicians contribute more liberally and freely of their substance, skill, and intelligence to the necessities, and even comfort, of the physically afflicted of the human race?

1013 Madison Avenue.

The Mattei Exposure.—The committee which was appointed some time ago to investigate the Mattei system of curing cancer "without the knife," has found, as might have been expected, that it is pure humbug and quackery. The Matteists began to treat five cases of genuine cancer, but soon said that it would take too long to cure them, and wanted the committee to examine some cases which they claimed had been cured by them. This the committee naturally refused to do, having not the slightest proof that the persons presented had ever had cancer. Finally the Matteists refused, with a great show of indignation, to permit the investigation to go on, alleging that the committee had broken faith by speaking of the course of the experiments before they were concluded. The chairman of the committee, Dr. G. W. Potter, publishes these facts in the *British Medical Journal* of August 13, 1892, and concludes as follows: "Matteism, in the deliberate judgment of the committee, consists exclusively of vulgar, unadulterated, unredeemed quackery. Mr. Stokes analyzed the 'electricities,' the potions of the Matteists, and found them to yield no other reaction than that of plain distilled water. The results of administering these substances to patients entirely coincided with the results of chemical analysis. Water is the potent magician which, when taken in unquestioning faith, makes some of the deluded victims of Matteism feel that they are relieved of their pains. Even the poor creature whose cancerous growth is ulcerated and excavated, and whom the Matteists themselves admit to be 'worse,' persists in declaring herself improved, and pathetically anticipates the day of her perfect cure."

OVARIOTOMY IN THE PRESENCE OF PERITONITIS.[1]

By WILLIAM S. CHEESMAN, A.M., M.D.,
AUBURN, N. Y.

No surgical emergency presents a picture more impressively grave than an ovarian growth complicated by an acute peritonitis. In such cases the older surgeons simply looked on, too much appalled to interfere, the disease making off with the patient under their very eyes. One of the earliest operators to offer surgical resistance in defence of his charge was Keith, who, after witnessing deaths by inflammation of the sac, cut in boldly and saved many lives. In these days one peruses scarcely any table of operation statistics involving one hundred cases without finding from one to four or five in which the operation was done in the presence of peritonitis, and a cursory review of the literature reveals many scattered single successes. Instead of the rule being, as in former days, to await the subsidence of the peritonitis before operating, it is growing to be—operate at once, and wait for nothing. And this for several reasons.

In the first place, the tumor is the *cause* of the peritonitis. By its mere presence, or by the friction, stretching, and contusion involved in its movement with every change of posture, an ovarian neoplasm is able to light up inflammation of the delicate lining membrane. The graver types of peritonitis are, however, usually produced by changes in the cyst. Inflammation of the sac, going on, it may be, to suppuration; rupture of surface cysts with irritating contents; twisting of the pedicle, producing necrosis and possibly bursting of the growth and outpour of gangrenous fluids; any of these may set up a peritonitis which cannot cease till its cause is removed.

A second reason for prompt operation is found in the fact that acute peritonitis itself may often be best dealt with by abdominal incision and drainage. As has been said by M. D. Mann, the peritoneum, like the pleura, should be drained when pus is present. The literature in support of this thesis is rapidly becoming extensive. In all lands surgeons are coming forward with records of operation triumphs. In tubercular peritonitis, general and encysted, in purulent puerperal peritonitis, even in the so-called idiopathic peritonitis of children and adults, the knife and drainage-tube are gaining ground on morphia and poultices. In the cases under consideration laparotomy is thus sound treatment for the peritonitis as well as for the tumor.

In the third place, nothing is gained, and everything is hazarded, by delay. Peritonitis is about the most serious thing that can happen after abdominal section, and that is already present. It cannot be made worse by operating. There is no question of jumping from the frying pan into the fire; you are in the fire already. Expectancy, delay, non-interference, are like the Governor's refusal to interfere with the execution of sentence of death. A few cases may survive the acute, and enter the chronic, stage of a peritonitis; but with the result that adhesions have become universal and highly vascularized, to the embarrassment, perhaps the defeat, of the operation when finally attempted.

The duty of prompt action seems thus plain. The sole question really demanding consideration is—How far can we go in our promptness? Shall we operate during shock? For this, I think, no hard and fast rule can be formulated. Each case must stand by itself. If the shock depend on twisting of the pedicle, or rupture of a suppurating cyst, reaction may never come. It is now or never. In selected cases, on the other hand, it may be safe to await reaction. The surgeon must be governed by that intuition which is the resultant of his knowledge of the case's history, his guess as to the cause of the sudden and tragic *dénouement*, his sizing-up of the patient's vital resources; in short, it is purely a question of judgment, with a capital J.

Shall we operate during acute peritonitis, or wait till the stress of symptoms has blown over? Knowlsley Thornton (*American Journal of the Medical Sciences*, October, 1888, p. 371) says: "The more I see of abdominal surgery the more I am convinced that operation during acute peritonitis is very dangerous, whereas in the subacute and chronic stage the patient bears the operation as well, or better, than with a perfectly healthy peritoneum." Here, again, it would seem wiser to leave the question to individual judgment based on knowledge of the peculiar features of each case.

All these considerations have in my experience recently received fresh emphasis from a case whose history was as follows:

Miss W——, aged twenty-seven, had for some time observed that her abdomen was enlarging, but had given the matter no attention. During the last Christmas holidays she suffered somewhat from pain, but this did not prevent her being out and about as usual. On January 4, 1892, she returned to her duties as a teacher in Chambersburg, Pa, where, on January 9th, she was seized with acute peritonitis. For a week her life was in great danger, complete intestinal obstruction with stercoraceous vomiting occurring. Out of this she made a gradual but imperfect recovery, and on February 11th, though her temperature had at no time been quite normal, her physician, Dr. Johnston McLanahan, allowed her to start for home. She bore the journey well, reaching Auburn February 14th.

I saw her, first, February 17th. She had then a temperature of over 100° F., and the abdomen was very tender. A letter from Dr. McLanahan was given me, stating his opinion that an ovarian tumor was at the bottom of the trouble. An examination verified his view. A fluctuating neoplasm reached above the umbilicus midway to the ribs, and well toward either flank. The uterus lay behind this mass. The menses were present at this time.

I determined to operate so soon as the patient was in a little better condition, and prescribed tonics and a generous diet. Two days later, however, she suffered a sudden relapse of her peritonitis, accompanied by great pain, and passed rapidly into collapse, with weak, rapid pulse, cold extremities and face, profuse cold sweats, and vomiting. This lasted thirty-six hours, when the pulse strengthened and the temperature rose to 102½° F. During the hours when it was doubtful how the shock would end, I had determined to operate just as soon as my patient could endure it, if that time ever came. Accordingly, with the beginning of her rally, preparations were immediately made. A room was stripped of carpet, hangings, and all needless furniture; walls and floor were washed with soap and bichloride solutions, the patient was bathed and douched, and on February 25th I operated, assisted by Drs. A. S. Hickey, F. H. Parker, and J. M. Jenkins.

The patient's temperature when she was placed on the table was 100½° F.; the pulse 120, and of fair quality. The usual shaving and cleansing with soap and water, ether, alcohol, and bichloride, were fully carried out. Instruments had been boiled in soda-water.

A four-inch incision was made. On opening the peritoneum a large amount of coffee colored serum gushed out. The membrane itself was intensely red, and covered with patches of lymph. The intestines were glued together. The cyst-wall, roughened and red from peritonitis, at once presented, and I tapped it, giving exit to a black, grumous material. The cyst was drawn forward through the incision as fast as it could be emptied, and freed. Adhesions existed everywhere, mostly young and easily broken by the fingers, but in the true pelvis they had become strong, and some force had to be used to break them. A small surface-cyst was here found ruptured, its thick, dark contents lying in the *cul-de-sac*. I could not be certain whether I had torn it, or whether it

[1] Read before the Medical Association of Central New York, May 11, 1892.

had burst spontaneously before the operation, and perhaps been the cause of the sudden collapse of the preceding few days. The pedicle was ligated with sterilized braided silk, and the cut surface cauterized with the Paquelin. The other (right) ovary was healthy. The tearing loose of so extensive an adherent surface was followed by free oozing of blood. The abdomen was repeatedly douched with hot boiled water till hemorrhage ceased. Iodoform gauze was then packed into the *cul-de-sac* and drawn through a glass drainage-tube. Wound closed with sterilized silk. Iodoform gauze dressing. Time of operation, fifty minutes.

Considerable shock followed. The temperature fell to 96½° F., the pulse ran feeble at 122, but by afternoon reaction had begun Some pain was complained of, and quieted with morphia. The next day the temperature reached 103°, but fell by evening to 99½° F., and never afterward rose above 101° F., and that but once. The bowels moved freely on the third day. Nausea gave no trouble. There was considerable oozing of bloody serum for several days. The glass tube came out on the fifth day, and a rubber one took its place for a time, after which gauze drainage was used till the drainage tract closed. Sutures were removed the eighth day, complete primary union having occurred.

Convalescence was uneventful. A slow and gradual fall of temperature, which did not remain at the normal throughout the day until the third week, registered the gradual subsidence of the peritonitis. At the end of four weeks the patient was able to be about as usual.

THE TREATMENT OF CHRONIC NERVOUS DISEASE IN PATIENTS OF THE RHEUMATIC DIATHESIS.

By ARTHUR C. BRUSH, M.D.,

BROOKLYN, N. Y.

The etiological relationship of the rheumatic poison to the various forms of acute and chronic nervous disease has long been recognized; but its importance as an indication as to the therapeutic measures to be employed has not received the attention which the results obtained in the following cases would seem to justify.

In the set of cases to which I wish to call attention we have the symptoms of the rheumatic diathesis preceding and accompanying those of the nervous disease; and, though these cases are not uncommon, writers seem to have confined themselves almost exclusively to the treatment of the latter disease, ignoring, except in the neuralgias, the cause which lies behind the trouble.

By the rheumatic diathesis I mean those cases which suffer from frequent attacks of pain and stiffness in one or more joints, sometimes swelling and redness, irregular pains referred to the bones and fibrous structure, cephalalgic, neuralgic, and myalgic attacks. They are also apt to suffer from digestive disturbances, and are irritable and depressed. They are usually worse before and during damp weather.

The rheumatic poison has a selective action upon the connective structures of the body, causing in them at first congestion, and, if long continued, hyperplastic inflammation; and these are the pathological changes found in the delicate connective tissue framework of the nervous system in the set of cases now under consideration.

We would seem, then, to have a certain number of the hyperplastic inflammations of the brain and cord whose cause is one that can sometimes be removed or held in check by the use of anti-rheumatic drugs. I do not mean that the nerve-cells which have undergone parenchymatous degeneration as the result of the pressure produced by the formation of such new connective tissue will be restored, but that we may be able to check the further formation of such deposits, or remove them, or at least to relieve the local congestion, and thus remove the pressure effects.

In the following cases it will be seen that they presented a well-marked rheumatic history preceding the development of the nervous disease, that the treatment was principally an anti-rheumatic one, that each exacerbation of the rheumatic symptoms was accompanied or followed by a similar one of those of the nervous disease, and that the symptoms of both improved under the use of anti-rheumatic remedies.

That the joint symptoms found in these cases were not those often found in chronic interstitial disease of the cord is evident, for it will be seen that they existed a long time before the development of the nervous symptoms, while those of nervous disease occur late in the course, and that they were all characterized by local pain and redness, while acute symptoms are absent in typical trophic joint-disease; and that they were most constant in the small joints of the hands and feet, while the others are most common in the knee and hip.

Of course it is possible that the improvement in these cases was due to the occurrence of one of those periods of improvement so often found in them; but the fact that it occurred in all of them after an anti rheumatic plan of treatment was commenced, seems to suggest that it was not a mere coincidence, but due to the treatment employed.

The following four cases are the ones in which this plan of treatment has been employed:

Case I. *Locomotor Ataxia.*—H. H——, aged forty-eight; married. First seen June 11, 1891. He has suffered from subacute rheumatism affecting the small joints of the hands and feet for the past ten years, which show the characteristic changes. His present trouble has existed over a year. Complains of severe shooting pains in the legs and occiput; sometimes severe gastric and vesical pains accompanied with vomiting and dysuria. Eyesight poor and pupils minutely contracted. Patellar reflex diminished. Feelings of numbness in the feet. Frequent seminal losses. Gait ataxic. Cannot stand with the eyes shut or place finger on the end of his nose. During the past few months he has developed an ataxic aphasia. Memory very poor, and well marked melancholia. Ordered sod. salicyl., gr. x., three times a day.

September 29th.—Patient gradually improved until yesterday, when he developed pain, redness and swelling in the feet and hands, which was followed by a return of his nervous troubles. Medicine continued.

October 13th.—Patient slowly improved since last note until two days ago, when both his rheumatic and nervous symptoms became much worse.

November 19th.—Condition unchanged since last note, and there is now also constant and severe pain in his hips and knees. Ordered pot. iodid., sod. salicyl., and colchicum.

March 17th.—Patient has been kept constantly on the same treatment since last note, and steadily improved. To-day he has no rheumatic symptoms, or neuralgic or visceral pains. Eyesight improved, and pupils normal. Tendon reflex diminished. No sensory disturbauces. Ataxic symptoms much improved, especially the aphasia. Memory improved; no melancholia.

Case II. *Multiple Cerebral Sclerosis.*—J. G——, aged fifty-seven; United States; widower. First seen October 13, 1891. He has suffered from rheumatic attacks since the war. Thinks his nervous troubles commenced about seven years ago. Has a well-marked tremor, increased by voluntary motion in the muscles of the arms and depressors of the jaw. Complains of weakness in the legs, and walks with a cane. Gait slightly ataxic. Articulation slow and monotonous. Memory poor, confusion of thought, vertigo, and constant headache, with insomnia and melancholia. Eyesight poor, cornea clouded, pupils contracted. There is loss of sensation in the parts supplied by the right musculo-spiral nerve. Constant pain in the lumbar region, pain and stiffness in the hip-joints and small joints of the hands and feet, which are also swollen and tender. Ordered sod. salicyl.

November 19th.—All his symptoms had markedly improved up to three days ago, his muscular tremors being hardly noticeable, and the anæsthetic area disappeared, when he developed a sharp rheumatic attack, which was followed by a return of his nervous symptoms with increased violence.

December 12th.—All the symptoms improved except the insomnia, headache, and pain in the back.

December 29th.—Symptoms unchanged, except increased vertigo, and he is very dull and apathetic. Ordered pot. iodid., sod. salicyl., and colchicum.

January 12th.—Marked improvement; no rheumatic symptoms. Ordered strychnine and quinine.

January 26th.—Rheumatic symptoms returned, with increased tremor in the right hand. Ordered sod. salicyl. resumed.

March 15th.—Marked improvement. No joint symptoms. Eyesight and memory much improved. No muscular tremors. Walks without his cane. Feels bright and cheerful.

March 29th.—Complains of dull pains in the bones of his legs, and return of tremors in the right arm and left gluteus maximus. Ordered pot. iodid., sod. salicyl., and colchicum.

April 12th —No rheumatic symptoms, but nervous ones are increased, with insomnia and drowsiness. Ordered pot. iodid., liq. pot., tr. gent., and syr. sarsaparil.

April 28th.—The only symptoms to-day are slight insomnia and drowsiness, with tremor in the right arm and pain in the back.

May 26th.—Tremor and pain unchanged, no insomnia or drowsiness. Ordered salol.

Case III. *Multiple Cerebral Sclerosis.*—M. D——, aged fifty; United States; married. First seen July 7, 1891. Has had frequent attacks of acute articular rheumatism for the past twenty years; her nervous symptoms have existed for several years. Complains of vertigo, mental confusion, lightning pains in the legs, and a feeling of some soft body between the foot and the ground. Well-marked ataxia of both arms and legs, and tendon reflex almost absent. Marked muscular tremors in the arms, made worse by voluntary effort. Speech slow and often incoherent. All the joints of the left leg are swollen and tender. Ordered sod. salicylate.

September 15th.—She had improved steadily, especially her ataxic symptoms, and the tendon reflex was much increased until a week ago, when she developed rheumatism in both knees and ankles, and all her nervous symptoms became worse.

November 7th.—Mental condition improved. Only disturbance of sensation is pain in the right lumbar region. Muscular tremors and ataxia improved. No rheumatic symptoms. Ordered strychnine, quinine, and arsenic.

December 26th.—She has had an attack of acute rheumatism in the left arm, followed by increased muscular tremor, vertigo, insomnia, cephalalgia, and pain in the back. Ordered sod. salicyl.

March 19th.—Rheumatic symptoms disappeared two weeks after last note, and the tonic treatment was resumed, with steady improvement. There is now no insomnia; confusion of thought, memory and speech are normal. There is slight lumbar pain, muscular tremor on motion, well marked ataxia, and diminished tendon reflex.

Case VI. *Locomotor Ataxia and Spinal Meningitis.*—D. M——, aged forty-nine; United States; married. First seen July 14, 1891. He has had frequent attacks of rheumatism since his tenth year. Nervous troubles commenced about two years ago. Complains of loss of memory, confusion of ideas, and insomnia. Eyes congested, night blindness, loss of accommodation, and contraction of the pupils. Tinnitus aurium. Slight ataxic aphasia. Pain over the dorsal spine, girdle sensations, and lightning pains in the thighs. Slight ataxia of both arms and legs, with unnatural fatigue and a sensation of constant coldness of the feet. Loss of sexual power. Frequent and imperfect micturition. Bowels constipated. Ordered potas. iodid., sod. salicyl., and colchicum.

July 18th.—No insomnia. Neuralgic pains in left face and neck.

July 26th.—Intense pain and rigidity of the spine, muscular cramps and neuralgic pains in the limbs, and increased insomnia. Ordered pot. iodid., liq. potas., and blister over the spine.

August 1st.—No spinal pain or rigidity. Pain, swelling, and redness about the right shoulder and ankle-joints. Ordered sod. salicyl., pot. iodid., and colchicum.

August 27th.—Rheumatic symptoms improved, nervous ones worse, especially the ataxic, and also has frequent attacks of cardiac palpitation and dyspnœa.

September 5th.—No rheumatic symptoms, and nervous ones improved.

November 28th.—Patient has been kept steadily on the same treatment since last note, and has had but one slight rheumatic attack. His nervous symptoms are about the same. Ordered strychnine, arsenic, and quinine.

January 9th.—Steady improvement since last note; has had two slight rheumatic attacks, easily controlled by sod. salicyl.

March 22d.—Patient has now no insomnia or confusion of ideas. Articulation much improved. Some pain over dorsal spine, but no other abnormal sensations. Muscular co-ordination and tendon reflex normal. No sexual desires. Bladder and rectal troubles about the same.

April 9th.—Pain and swelling in the ball of left great toe. Misplaces words when writing. Muscular tremors after a few minutes' exertion. Ordered pot. iodid., sod. salicyl., and colchicum.

April 14th.—No rheumatic symptoms, nervous condition about the same, with irregular heart action, and once in a while he has a long, sighing inspiration. Ordered strychnine and arsenic.

April 26th.—Patient has no objective or subjective symptoms to-day, except a feeling of languor. Ordered Bland's pill.

May 27th.—Patient has remained well since last note, and has returned to work.

These four cases, taken from my clinic at the Brooklyn City Dispensary, are the only ones which I have been able to retain a hold upon long enough to obtain any satisfactory results. Of course, belonging as they do to the rheumatic diathesis, they are liable at any time to a return of that disease, and, as a consequence, of their nervous troubles; but I think the result thus far obtained would warrant its further trial in these otherwise hopeless cases.

Hydrastinin in Epilepsy.—V. G. Kiseleff (*Vratch*, No. 20, 1892), experimenting on dogs and guinea-pigs, has found that intravenous injections of hydrastinin (see *Epitome*, April 23, 1892, p. 66; and May 28th, p. 87), even in small doses (0.04 gramme per 1 kilogramme in dogs), distinctly lowered the excitability of the brain cortex, and mitigated or prevented epileptic fits induced by absinthe. These observations induced him to try hydrastinin in six cases of epilepsy. It was given internally, in an aqueous solution, from one-fifth to one-half grain for a dose, up to one or two grains a day. In four patients, in two or three weeks the fits decreased both in frequency and in intensity, while in the remaining two the treatment was less efficacious. No unpleasant accessory effects were noticed. F. Kh. Gadziacki also employed hydrastinin in a case of epilepsy, but without result. The hydrastinin treatment of epilepsy, as well as of hydrophobia and strychnine poisoning, was first suggested by P. I. Arkhangelsky (*St. Petersburg Inaugural Dissertation*, 1891, No. 59), whose experiments on animals showed that the alkaloid ($C_{11}H_{12}NO_2$) possessed powerful antispasmodic properties.—*British Medical Journal.*

Progress of Medical Science.

Removal of a Bony Growth from the External Auditory Canal by Means of Drills.—Dr. Samuel Sexton reports a case of the above which he saw recently in the practice of Sir William B. Dalby, of London. The growth, which was a hyperostosis quite occluding the right external auditory canal in a gentleman forty-two years of age, was first pierced by a small drill run by an American dental engine, and then several larger ones were introduced, until the bony tumor was honey-combed. In a few days the remaining mass came away, and when Dr. Sexton again saw the patient, three weeks after the operation, the external auditory canal was freely open and the parts were healed. These growths in the ear are said to be of frequent occurrence in England.

Psoriasis a Neurosis of the Skin.—The *British Journal of Dermatology*, October, 1891, contains an abstract of a highly instructive and original paper recently published by Dr. A. G. Polotebnoff, in which the author expresses the opinion that psoriasis is the result of nervous disturbances, that it is a neurosis of the skin. Other theories in regard to cause he carefully considers, such as heredity, parasitic influence, hereditary syphilis, arthritism, the herpetic diathesis of the French school, and infectious disease, and finds these unsatisfactory and insufficient. Psoriasis is not an inflammatory process. It is connected with dilatation of the vessels of the papillæ of the skin, and accompanied by an increase in the formation of epithelial cells. Changes in nerve tissue have not been described, probably because not properly sought for. The original Russian publication records sixty-seven cases, arranged for convenience in eight classes. Of these the English journal reviews twenty-eight cases, in which severe headache, marked neuropathic affections in the family, coincidence of eruption with severe psychic shock, evident clinical abnormities in the nervous system, diseases of bones and joints, typhus fever, and intemperance comprise the origin or manifestation of nervous abnormity. The symptoms in all may be classed as vaso-motor neuroses. They refer chiefly to the action of the heart and blood-vessels, to temperature, and to the action of sweat glands. Perspiration is entirely in abeyance in the diseased spots, though there is no alteration in the glands themselves. Treatment is directed almost exclusively to the nervous system. The drugs indicated, whenever there is prominence of acute nervous symptoms, are bromine salts, bromide of potassium, bromide of sodium, and hydrobromide of quinine. As soon as acute symptoms are allayed, and even before, Dr. Polotebnoff gives arsenic, a drug that has special affinity for nerve tissue. Skolobusow found in acute and chronic arsenical poisoning that the brain and medulla contained thirty times as much arsenic as the liver and muscles. Lesser's experiments are still more conclusive. The dose of arsenic is gradually increased until half a grain a day is taken for a week or a fortnight. Relapses must be looked for, as primary vaso-motor and functional neuroses are not cured in a day. Inveterate cases where there is much nerve change resist arsenic even in large doses. Ergot the author considers worthy of more attention than it has yet received. Cold packs, tar, chrysarobin, pyrogallic acid are also useful. Though applied externally, these may act as nervine tonics through the skin.

Curetting in Lupus.—Dr. Broca's communication to the French Dermatological Society upon the subject of sharp curetting for the amelioration of lupus appears in the *Mercredi Médical*, December 16, 1891. This procedure, common in Germany, where it was first introduced by Volkmann, has never met with much favor in France. Deep scars are said to follow it, and the patient is supposed to risk acute tuberculosis through traumatic auto-infection. While not partial to this method of treatment, Dr. Broca considers it indicated in certain cases. Those that he cites show interesting results. In the first, the disease appeared upon the back of the left foot, rapidly extending over the anterior surface of the leg, knee, and thigh. To treat such a condition by galvano-cautery or scarificator would be an affair of months or years. New nodules would appear as rapidly as others could be effaced. This extensive surface was curetted at a single operation under chloroform, with cicatrization of the whole area within three weeks. This, without suppuration or significant rise of temperature. In the opinion of the operator, deep and deforming scars are due to suppurating processes. The technique of this operation is simple. First, there is energetic curetting of the soft layers. Then the hard, fibrous tissue beneath is removed. In the foregoing case, this removal was from the large toe up to the thigh, thick tampons of antiseptic cotton being applied instantly to the denuded surface. Hemorrhage being arrested, sterilized compresses were applied, the parts being touched by a 1 to 10 solution of chloride of zinc, and then covered with iodoform gauze. In the other cases, one in a youth of twenty, presenting lupus of the face and forearm, and a boy of fourteen, in whom lupus of the face had existed thirteen years, the operation proved equally successful. None of these patients are cured, the radical cure of lupus being as yet unknown. But they are greatly benefited, their apparent cure requiring only three or four weeks. Surgical interference requires less time than other methods of treatment, and in these cases presented the most rational plan of procedure.

Vulvar Pruritus Cured by the Constant Current.—In the *Union Médicale*, November 10, 1891, quoting from the *Revue de Thérapeutique Générale et Thermale*, 1891, a cure of pruritus of the vulva is recorded by Dr. Cholmogoroff. The patient, who had suffered two years from pruritus, was thirty-six years of age, married at twenty-four, and had one child. Menstruation, beginning at the age of thirteen, had always been regular. There was no sugar in the urine, and no utero-ovarian trouble of any kind. Vaseline with cocaine and carbolic acid lotions procured some relief. The condition was always much aggravated just before menstruation, varying in intensity at other times. Electricity was employed, with the effect of relieving the patient greatly after the fifth application, and causing the trouble to disappear entirely after the sixth. A hard rubber electrode negative, with a metal tip, was introduced in the vagina, and a flat electrode applied over the affected surface. The current, used for ten minutes each time, varied from fifteen to twenty-two milliampères. There was no return of the difficulty up to date, six months after its cure.

Lichen Planus Treated by Hydrotherapy.—Among interesting items of correspondence contained in the *Journal of Cutaneous and Genito-Urinary Diseases*, January, 1892, there is an account of Jacquet's case of lichen planus treated by tepid douches, followed by a short cold affusion. This treatment, instigated after the complete failure of glycerole, of tartaric acid, baths, and Fowler's solution, allayed nervous symptoms in a few days, restored sleep and appetite, and calmed all pruritus. The eruption began to diminish in about three weeks. After slight recrudescence it disappeared entirely in six weeks. This result emphasizes anew the close relation existing between modifications of the nervous system and lichen planus, though the connection between the cerebro-spinal system and the cutaneous lesion is as yet unknown.

Aleuronat for Diabetics.—Aleuronat is the name of a vegetable albumin introduced by Hundhausen, which Erbstein has found very useful as a substitute for bread in diabetic cases. It is a dry, yellow powder, without taste or smell, containing eighty per cent. or more of nitrogenous elements and only about seven per cent. of carbo-hydrates. He employs it in preparing soups and other dishes, as well as in making bread, which shows sixty-six per cent. of nitrogenous matter.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, September 10, 1892.

THE CHOLERA OUTLOOK.

NOTWITHSTANDING the extraordinary precautions taken to prevent the entrance of cholera into New York we are forced to view the present outlook with grave concern. With the best of promises against invasion, it behooves us to be prepared in time for the worst. The many ways in which the strictest quarantine can be oftentimes evaded, the numerous avenues through which a plague may enter our unprotected land routes, the difficulty in educating the public to a proper sense of responsibility in protective measures, the pecuniary interests that are in direct antagonism to the restriction of personal liberty in travel, and the pressure to overcome the necessary hindrance to commercial transfers, are factors which weigh with the greatest possible force against the best intentions of the most trustworthy officials.

Such is the situation at the present writing, and, while hoping for the best, we need not be surprised at any time to hear that the dreaded plague has surreptitiously appeared in our streets. Once here, we may have every reason to view the prospect with the greatest alarm. With commendable zeal the different departments have worked with the energetic Health Board in preparing for the attack; but we must not shut our eyes to the fact that there is still an abundance of filth in different quarters in, and out of doors, to furnish the proper soil for a most formidable epidemic.

Whatever may be the outcome of our anxiety, it is quite certain that the health authorities and the medical profession will be ready for any emergency. Suspicious cases will be anxiously watched and speedily reported, and everything will be done to aid the sanitary officials in their endeavor to arrest the progress of the dreadful malady.

Since the last epidemic visited this city we have learned very much of the natural history of the disease, and are consequently the better able to fulfil the indications for treatment. It is well for the public to know that as yet no cure-all has been discovered. Notwithstanding the general principles of medication are quite clearly understood, each case must, from a strictly scientific stand-point, be treated on its own merits. Wholesale medication, as a rule, is bad, even when emergencies might appear to make such a measure necessary. Self-prescribing is even worse, and should be discouraged by all those in authority. Patent mixtures and so called specific remedies for cholera should be avoided almost as strictly as the plague itself. Those who may unfortunately be stricken will not lack for competent medical treatment, and there will be no necessity for newspaper prescriptions, nor consequent loss of precious time in the applications of the proper remedies to individual cases. It must be borne in mind in this connection that the cases seen the earliest in the attack are those which are benefited, while the remainder are apt to drift into collapse and furnish the fifty per cent. death-rate.

Much has already been done by the health authorities in educating the public in precautionary measures against the spread of infection, but there is evidently much still to be accomplished before we can guarantee that the disease will not spread in a properly receptive soil in spite of the best efforts to the contrary. It is quite certain that the poison is carried by clothing, food, and water which have become in some way infected by the ejecta of the sick; that the bacilli find their way into the body through the alimentary canal, and eventually exert their toxic influence on the nervous centres, and that thoroughly systematic preventive antisepsis reduces the danger to a minimum. That it is not absolute, however, is oftentimes proven by a fixed limit of epidemic influence and a graded march of mortality from the beginning to the end of the visitation.

Experience has proven that with proper care the worst epidemic can speedily be brought within bounds, and that the number of victims attacked can be steadily reduced. While there is no possibility that our health board will follow the melancholy example of the authorities at Hamburg, in negligently allowing the scourge to gain a headway, there is abundant encouragement for the adoption of the stringent systematic measures employed in Berlin in checking a threatened epidemic. In order, however, that such results may be possible, each citizen, in his individual capacity, should do his best to conform to hygienic rules, and willingly and promptly set his house in order.

On the other hand, a great deal can be accomplished by properly guarding one's self against an attack. Full health in the individual is, perhaps, the greatest safeguard of all. Bacteriologists who test and physicians who treat contagious diseases are always careful to be well-nourished and to make their visits immediately after meals. Their careful attention to hygienic rules undoubtedly gives them an immunity which the ordinary layman can seemingly neither appreciate nor enjoy. In every epidemic the weaker ones are attacked, while the stronger escape and offset the usual ratio of mortality. So whatever may come, the one who keeps his health-standard to the highest point is surest of escape.

THE QUESTION OF SEX IN THE BRITISH MEDICAL ASSOCIATION.

WE noted recently, as an interesting sign of the times, that the German Universities were on the eve of admitting women to their sacred precincts and giving them equal privileges with men of drinking in the words of wisdom as they fell from the lips of the learned professors. Another event of like import was the vote taken at the Nottingham meeting upon the question of admitting women to membership in the British Medical Association.

Fourteen years ago some ungallant male member of the Association proposed that a clause be added to the by-laws, providing that "no female shall be eligible for election as a member of the Association," and this proposition was agreed to by a large majority of those present at the meeting. Mrs. Garrett Anderson had been elected a member before the passage of this amendment in 1878, and, as nothing was said about expelling her for the crime of being a woman, she stayed on. Now she has had the satisfaction of seconding a resolution to expunge this offensive clause, and of seeing the resolution passed almost unanimously.

It is worthy of note that the question was forced upon the attention of the Association by the action of some Colonial branches which had welcomed women to membership. But that only accelerated matters a little, for the change was inevitable, and all the old fogies in the Association could not have delayed it much longer. At the time of the Bath meeting, when the clause was adopted, there were but eight women practitioners in the United Kingdom, whereas now there are one hundred and thirty in the *Register*, and one hundred and forty more women are studying medicine at various schools in Great Britain and Ireland. We have no doubt there were more than the four who voted against the amendment who would have been glad to do so had they dared. They saw, however, the absurdity as well as the impossibility of keeping women out of the Association when they could not keep them out of the profession, so they let them come in. It was amusing, though, to note with what a show of magnanimity, some of the speakers yielded to the inevitable, as though the change was entirely of their own doing, and was a spontaneous expression of their sense of justice and right. It pleased them, however, and the women who have carried their point don't care.

CROTON WATER.

One of the most certain means of preventing the spread of diseases such as cholera and typhoid fever is an abundant supply of water uncontaminated by any of the specific causes of these affections. And, unfortunately, it is extremely difficult for any city to obtain a perfectly pure water-supply, and one that shall in every contingency be above all suspicion. This is as true of New York as of other cities, but so much that is exaggerated and unfounded has been written against the Croton water that it seems worth while to say a few words concerning it.

The first thing to remember, and which seems to have been forgotten by some writers in the daily press, is that water cannot run up hill. There might be a thousand cases of cholera every day in this city, and if there was none in the area comprising the Croton water shed, the water-supply of New York would be irreproachable as far as relates to cholera. Again, because a water is discolored, as we must confess ours often is, it does not follow that it contains the germs of disease. The *Journal of the American Medical Association*, in commenting recently on the Croton water, said: "Albuminoid ammonia is reported by the official chemists to show a decided increase, while the presence of vegetable matter in excess is revealed by the microscope. If this condition persists, a reported increase in cases of enteric fever must be expected among those who use unfiltered and unboiled water."

Misery doubtless loves company, the fallen are prone to deny the existence of virtue anywhere, and Chicago might not be overcome with grief if New York had an epidemic of typhoid fever, but that is no excuse for talking nonsense. Albuminoid ammonia and vegetable refuse are very undesirable ingredients of drinking-water, but we have yet to learn of a case in which they were the cause of typhoid fever.

Our water is far from being what it should be. There is a large population in the district from which it is derived, and there are many nuisances allowed to exist there which ought to be abated. The water will be exposed to contamination if cholera becomes epidemic in New York, for it is highly probable that, in that event, some cases would make their way to the Croton water-shed. But even then there would probably be no great fouling of the water, for the sick would, without doubt, be properly taken care of, and their discharges would be disinfected. Moreover, a bucketful of cholera dejecta thrown into one of the branches of the Croton River would afford a pretty small per capita allowance of comma bacilli for New York City, even should none be lost on the way, or be destroyed by the other bacteria which are present in fairly generous amount in the Croton.

We have absolutely nothing to object to in the filtering and boiling of all water for drinking, as well as for washing purposes. It is an excellent practice in any city, and whether disease is present or not, and as such we commend it heartily, and would urge its universal adoption in case cholera breaks out here. But we do object to the teaching of false doctrine, even when its dissemination might frighten people into taking care of themselves.

CHOLERA AND ICE.

Dr. Daremberg, who is rather inclined to aphorisms, recently told the Parisians to boil their ice. He referred to the artificial ice which is made, by one company at least, from the water of a stagnant pool formed by the overflow of the Seine after it has received the contents of over fifty sewers. This water is apparently frozen without previous distillation, and thus, as Dr. Daremberg again neatly puts it, while Paris poisons the suburbs, the suburbs also poison Paris.

This expression, "boil your ice," seems to have tickled the professional mind, for it has been pretty extensively plagiarized in various interviews *re* cholera, its reference to poorly made artificial ice being, however, lost sight of. Thus one of London's medical baronets was asked not long ago, by a reporter, what advice he would give to the public in this time of peril. The learned gentleman, according to an English contemporary, "advised the young man, if he wished to avoid the dreaded disease, not to drink water contaminated with cholera germs or sewage, and he facetiously added that he would recommend him to boil his ice before using it." This was neatly varied by a physician in this city, who was reported by a daily paper to have tersely summed the working rules appropriate to a cholera epidemic into one: "Boil everything —except the ice, and throw the ice away."

That ice is a good culture medium for the comma

bacillus or that this microbe can worm its way into the centre of a block of ice that was frozen and cut last winter in England or America, is something rather startling to think of, and probably the gentlemen who have repeated Dr. Daremberg's "quaint saying," as the *Lancet* approvingly calls it, did not think of it at all. It is true that ice may contain the germs of typhoid fever and other diseases, and the immoderate use of even pure ice may disorder digestion, and thus prepare the way for the lodgment of the cholera bacillus; but to imply that last winter's ice is liable to be the direct carrier of the poison, in the same sense as contaminated milk or water, is absurd.

THE TWENTY-DAY ORDER.

We are pleased to learn that the reported antagonism of Health Officer Jenkins to the order of twenty days' quarantine by the President was more apparent than real, and that the full time for detention of suspected vessels will be duly enforced. The discussion of what may be considered States' rights in this matter is, under present circumstances, very properly ignored. Just now the health officer has a very responsible duty to discharge, and it does not behoove him to add to its weight by taking any accommodating chances. Instead of being tempted to shorten the period of quarantine, every opportunity should be taken to lengthen it, and thus make assurance doubly sure. This new decision will bear with force upon travellers, but the greater interests at stake are alone to be considered in the present emergency.

News of the Week.

CHOLERA NEWS.

A Fact With a Moral.—Dr. E. O. Shakespeare, in his "Report of Cholera in Europe and India," calls attention to the significant fact that cholera epidemics in Madras avoid Pondicherry, although it lies directly in their course. The explanation is to be found in the purity of the water-supply, which is derived from artesian wells.

Cholera Regulations on the Bremen Line.—The North German Lloyd Steamship Company announce that each of the steamers of that line will carry two surgeons during the prevalence of the cholera. The vessels will be thoroughly disinfected each day. Baggage will be disinfected before it is put aboard the steamers. During the voyage only water that has been boiled, or with which muriatic acid has been mixed, will be supplied to the crews and passengers.

A Volunteer Relief Corps.—The directors of St. Mark's Hospital propose to form a physicians' and nurses' volunteer corps to give free medical aid, nursing, and to supply medicines to poor persons residing in the district below Fourteenth Street east of Broadway, in case cholera should become epidemic in the city.

The United States of Colombia.—The Columbian Federal authorities issued an order on August 29th closing the ports on the Atlantic coast of Columbia to all vessels arriving from ports infected with cholera. This puts a stop at once to all commerce with Germany, but the steamers from France sail usually from St. Nazaire, so that they will not be shut out at present. If cholera should appear in New York the boats of the Pacific Mail line would come under the exclusion rule.

The Action of Canada.—The Dominion authorities have given notice to the steamship companies that any vessel attempting to bring immigrants for the United States through Canada would be detained for the period of the United States quarantine. The Quebec Provincial Board of Health has passed a resolution forbidding until further notice the bringing, either by water or land, of immigrants or the effects of immigrants within the limits of the Province of Quebec; and also forbidding any vessel coming from a port infected with cholera, or having had any cases of cholera on board during the passage, to land at any place in the Province of Quebec, or to disembark either passengers, crew, baggage, or merchandise. Inspectors have been appointed at various places to see that these regulations are strictly obeyed.

The State Board of Health has, through its secretary, Dr. Lewis Balch, addressed the following circular to all the local boards throughout the State:

"Gentlemen: Your attention is called to the published report of cholera being in France, England, and Germany. None is yet stated to be in the United States or Canada. The danger of infection, however, can be considered sufficiently imminent to warrant all precautions. While it is particularly enjoined that unnecessary panic be avoided, you are requested to take all measures for the better protection of the public health, should the disease gain a foothold on this continent. If cholera is reported in Canada, you will make such arrangements as may be necessary for the proper inspection of trains and vessels coming from there into this State. Any cases of the disease found should be at once removed to a suitable place, and all persons exposed subjected to quarantine. If the exposure is not sufficient to warrant the detention of passengers, their names and destinations should be obtained and this department notified by telegram, that it may warn the health authorities interested."

Deaths at Quarantine.—Up to the morning of September 8th, there were eleven deaths from cholera among the passengers and crews of the three infected vessels since their arrival at Quarantine. On the same vessels thirty-one died at sea.

The Cholera in Europe.—The epidemic continues with unabated force in Russia and in Hamburg, although in the latter city as well as in Russia no reliance whatever can be placed upon the official returns of cases and deaths. It is worthy of note that, wherever the officials have trusted to a policy of concealment, there the disease has carried off the greatest number of victims.

The Health Board in New York has commenced to publish daily bulletins of the cholera. Up to the present they are as instructive as the celebrated treatise on the snakes in Ireland, and it is to be hoped that the resemblance between the bulletins and the treatise will continue.

Twenty-day Quarantine.—A circular has been issued by the Surgeon-General of the Marine Hospital Service, and approved by the Secretary of the Treasury and the President, imposing a quarantine of twenty days upon all vessels bringing immigrants to this country.

The Summer Corps of the Board of Health, whose two months' term of service has just expired, has been organized into an epidemic squad of sanitary inspectors, and assigned to duty in the tenement-house districts. They have been instructed to make a special search for diarrhœal diseases, and to report any suspicious cases.

Cremation of those Dead from Cholera.—Some of the German medical journals are agitating in favor of the compulsory cremation of all who have died of cholera, as the surest means of preventing further infection of the soil by the bacilli which their corpses contain. The health authorities of this port have disposed of the bodies of all those who have died of cholera at Quarantine by cremation.

Contagion through Flies.—If, as it appears to have been proven by experiment, flies may be the means of disseminating anthrax, tuberculosis, and other infectious diseases. they should be objects of especial suspicion during an epidemic of cholera. They should be excluded from the house as far as possible, and all articles of food and drink should be protected by screens from contamination by them.

The Hamburg Authorities, unless the cable does them gross injustice, have displayed a degree of criminal inefficiency, negligence, and deceit in dealing with the cholera epidemic, that is almost incredible. For two weeks the disease was in the city, the number of victims constantly increasing, before any warning was given, and even then it was said to be only cholerine, and of very little import. The origin of the epidemic in Hamburg is also directly traceable to the stupidity of the health authorities. There was a camp of Russian exiles, among whom cholera was raging, located on the banks of the Elbe near the city water-works, and the people in the camp were allowed to throw their slops and other filth into the river. It is said that over forty towns in Germany alone have reported cases of cholera imported directly from Hamburg.

Russian Emigrants, it is officially announced, will no longer be permitted to enter Germany.

Directions for Disinfection.—The following circular concerning disinfectants and their use has been prepared by the Health Board for distribution :

1. Roll sulphur (brimstone) for fumigation.

2. Copperas Solution.—This solution is made by dissolving copperas (sulphate of iron) in water in the proportion of one and a half pound to the gallon, and is used for disinfecting cellars, drains, sewers, areas, alleys, etc.

3. Zinc Solution.—This solution is made by dissolving four ounces of sulphate of zinc (white vitriol) and two ounces of common salt together in one gallon of water, and is used for disinfecting clothing, bed-linen, etc.

4. Corrosive Sublimate Solution.—This solution is made by dissolving eight grains of corrosive sublimate (bichloride of mercury) in a pint of water, and is used for disinfecting the discharges from persons sick with cholera and other diseases. As this solution is a dangerous poison, it should be prepared and used under the direction of a physician or chemist.

5. Chloride of Lime Solution.—Dissolve chloride of lime of the best quality in soft water, in the proportion of four ounces to the gallon. Use one pint of this solution for the disinfection of each discharge in cholera and typhoid fever. Leave the disinfectant in the vessel for at least fifteen minutes before throwing it into the vault or closet.

6. Premises.—Cellars, yards, stables, gutters, cesspools, closets, drains, sewers, etc., should be frequently and liberally treated with copperas solution. The copperas solution is easily prepared by hanging a basket or bag containing about sixty pounds of copperas in a barrel of water.

7. In the Sick-room.—The most available agents are fresh air and cleanliness. The clothing, towels, bed-linen, etc., should, on removal from the patient and before they are taken from the room, be placed in a pail or tub of the zinc solution, boiling hot, if possible.

All discharges should either be received in vessels containing corrosive sublimate or chloride of lime solution, or, when this is impracticable, should be immediately covered with such solution. All vessels used about the patient should be cleansed with the same solution. Unnecessary furniture, especially that which is stuffed, carpets, and hangings, should, when possible, be removed from the room at the outset ; otherwise they should remain for subsequent fumigation and treatment.

8. Fumigation with sulphur is the most practicable method for disinfecting the house. For this purpose, the rooms to be disinfected must be vacated. Heavy clothing, blankets, bedding, and other articles which cannot be treated with zinc solution should be opened and exposed during fumigation, as directed below. Close the rooms as tightly as possible, place the sulphur in iron pans supported upon bricks placed in washtubs containing a little water, set it on fire by hot coals or with the aid of a spoonful of alcohol, and allow the room to remain closed for twenty-four hours. For a room about ten feet square, at least two pounds of sulphur should be used ; for larger rooms, proportionally increased quantities.

9. Body and Bedclothing, etc.—It is best to burn all articles which have been in contact with persons sick with contagious or infectious diseases. Articles too valuable to be destroyed should be treated as follows : Cotton, linen, flannels, blankets, etc., should be treated with the boiling-hot zinc solution. Introduce piece by piece, secure thorough wetting, and boil for at least half an hour. Heavy woollen clothing, silks, furs, stuffed bed-covers, beds, and other articles which cannot be treated with the zinc solution should be hung in the room during fumigation, their surfaces thoroughly exposed, and pockets turned inside out. Afterward they should be hung in the open air, beaten and shaken. Pillows, beds, stuffed mattresses. upholstered furniture, etc., may be cut open, the contents spread out and thoroughly fumigated. Carpets are best fumigated on the floor, but should afterward be removed to the open air and thoroughly beaten.

The Floating Hospital of St. John's Guild has been turned over to the Board of Health to be used as a hospital for cholera patients, in case the disease appears in New York.

Salol is one of the multitude of drugs recommended as specifics in cholera. Dr. Löwenthal, writing in the *Deutsche Medicinische Wochenschrift*, recommends its use

very highly. He says the remedy was employed recently in the Philippine Islands, with the result that there were only three deaths in fifty-three cases.

A Potent Sanitarian.—The Ameer of Bokhara had ordered a cleansing of the city, but hearing that there was a revolt against this order on the part of the dirt-loving inhabitants, his Highness at once commanded the execution of every subject who did not carry out the new sanitary regulations within a week. A reasonably civilized modicum of this vigor in American cities would tend not to destroy men's lives, but to save them.—*Sanitary Era.*

"**Boil Your Ice**" is the advice given by Dr. Daremberg to the Parisians in view of the threatened invasion of cholera. The advice is not bad when it is remembered that one source of the artificial ice-supply of Paris is a pond supplied with Seine water, after it has been polluted with sewage, and which is not distilled before being frozen.

Visitors to the "People's Baths."—A year ago we described the new bath-houses known as the "People's Baths," erected in Centre Market Place by the "New York Association for Improving the Condition of the Poor." The matter was somewhat of an experiment, as it was not known whether the people in that neighborhood would avail themselves of the bathing facilities afforded there. It is very satisfactory to learn that the institution has been a success, as is shown by a report for the year ending August 16, 1892. The number of baths taken in that time was 61,226. Of this number of bathers there were 40,455 men, 7,575 women, 6,203 boys, 2,043 girls, and 4,950 small children. In all cases except those of small children there is a charge of five cents for each bath, and with this is given a piece of soap and the use of a towel. The receipts for the year from this source were $2,813.80.

Southern Surgical and Gynecological Association.—The annual meeting of this Association, which was to have been held November 8th, 9th, and 10th, has been postponed to the 15th, 16th, and 17th of the same month. It was thought wise to change the time of meeting because of the presidential election, which will take place on November 8th.

Dr. Georg Hermann von Meyer, formerly Professor of Anatomy in the University of Zürich, died in his native city of Frankfort-on-the-Main a few weeks ago. He was seventy-seven years old.

A Post-graduate Course for Nurses.—The managers of the New York Cancer Hospital, desiring to give nurses who graduate from small hospitals the advantage of a larger experience in surgical work, have established a post-graduate course of one year. Graduates in good standing may enter at any time. At the conclusion of their term of service a certificate, signed by the governors of the hospital and the attending surgeons, will be given, provided that their work has been satisfactory. Lectures by the attending staff and superintendent will be given, and each nurse will have an opportunity to witness operations, and be given a term of service in the operating-room. Further information concerning the course of study and requirements may be obtained by addressing the Superintendent, Anna M. Lawson, 106th Street and Central Park West. Surgeons and others desiring the services of trained nurses may obtain them by addressing the Superintendent in person or by letter.

The "Ontario Medical Journal" is the name of a new medical monthly published in Toronto, under the editorial charge of Dr. Orr. It is to be the official organ of the "College of Physicians and Surgeons of Ontario" (a society of physicians in the Province of Ontario), and will publish the transactions of that society.

The Canadian Medical Association will hold its twenty fifth annual meeting at Ottawa, on September 21, 22, and 23, 1892.

Dr. D. S. Lyon, of Winnemissett, Fla., was shot and fatally wounded on August 30th by deputy sheriffs, whom he fired upon when they attempted to arrest him for shooting his wife and daughter. He is supposed to have been temporarily insane. He was fifty-three years of age, a graduate of Yale College, and had studied medicine at the University of Virginia and in Berlin.

Professor v. Krafft-Ebing has been nominated by the Medical Faculty of the University of Vienna for the chair of psychiatry, left vacant by the death of Professor Meynert.

Professor Henoch, of Berlin, received the order of the Red Eagle, Second Class, from the German Emperor, and the commandership of the Norwegian order of St. Olaf, First Class, from the King of Sweden and Norway, on the occasion of his jubilee as a Doctor of Medicine.

Dr. Enoch Chase died in Milwaukee a few days ago, at the age of eighty-three years. He is said to have been the first physician in Milwaukee, having settled fifty-seven years ago on the site where the city was afterward built.

The Way it Comes.—The *St. James' Gazette* of August 29th, commenting on the cholera, says: "If we continue to allow foreigners to settle in our midst, we will have frequent epidemics." If the foreigners that "settle in our midst" are comma bacilli, there is no doubt that cholera will follow, and we can but admire the logical discernment of our grammatical contemporary.

A Bichloride Libel Suit.—Mr. Keeley, of bichloride of gold fame, has met with a want of appreciation in England, and has so far lost his temper in consequence as to bring a suit for libel against the *Lancet* and the *Medical Press and Circular*. The latter welcomes the action, which, it says, "will afford us an opportunity of calling public attention to what we firmly believe to be an attempt to delude the victims of an unfortunate and degrading habit into filling the coffers of an enterprising syndicate."

Dr. Ludwig Bandl, formerly Professor of Gynecology at the University of Vienna, died on September 2d at the Doebling Insane Asylum. In 1887 Dr. Bandl was transferred from Vienna to Prague, but broke down at his first lecture in the latter university, and was soon thereafter removed to the asylum where he died.

A Case of Death from Chloroform occurred not long ago in Liverpool. The patient was a woman aged thirty-four, who was advised to take chloroform before having some teeth extracted. She had inhaled less than thirty drops when her pulse became weak, and she had an epileptic fit and died.

Reviews and Notices of Books.

A New Pronouncing Dictionary of Medicine: Being a Voluminous and Exhaustive Handbook of Medical and Scientific Terminology, with Phonetic Pronunciation, Accentuation, Etymology, etc. By John M. Keating, M.D., LL.D., Fellow of the College of Physicians of Philadelphia; Vice-President of the American Pædiatric Society; Ex-President of the Association of Life-Insurance Medical Directors; formerly Visiting Obstetrician to the Philadelphia Hospital (Blockley), and Lecturer on the Diseases of Women and Children; Consulting Physician for the Diseases of Women, St. Agnes' Hospital, Philadelphia; Gynecologist to St. Joseph's Hospital, Philadelphia; Editor of "Cyclopædia of the Diseases of Children," etc.; and Henry Hamilton, Author of "A New Translation of Virgil's Æneid into English Rhyme;" and co-author of "Saunders's Medical Lexicon," etc. With the collaboration of J. Chalmers Da Costa, M.D., and Frederick A. Packard, M.D. With an Appendix Containing Important Tables of Bacilli, Micrococci, Leucomaïnes, Ptomaïnes; Drugs and Materials Used in Antiseptic Surgery; Poisons and their Antidotes; Weights and Measures: Thermometric Scales; New Officinal and Unofficinal Drugs, etc., etc. Philadelphia: W. B. Saunders. 1892.

A new medical dictionary at this day, in order to have any *raison d'être*, must, in default of general perfection, have at least one special point of excellence wherein it surpasses all its numerous rivals already in the field. The compilers of the present work seem to have recognized this necessity, and to have selected orthoepy as the distinguishing feature of the book and the one which, through its undeniable excellence, should stamp the lexicon at once as an authority. This conclusion is forced upon us by the title of the book, by the fact that the preface is devoted entirely to a consideration of the rules of pronunciation, and by the claim there made that the book is "a pronouncing dictionary in the true sense of the word." We are led, therefore, to examine this feature first, in order to see how far the claim to accuracy and authoritativeness is sustained by the work itself. Unfortunately, we have not long to search before finding that the book is full of errors. In the preface (p. 11) we find four words wrongly accented in one line. These are, of course, errors due to careless proof-reading, but careless proof-reading in a lexicographer is as reprehensible as ignorance, for the reader cannot be supposed to distinguish between printers' errors and authors' blunders, and is misled as readily by the one as by the other. Other evident proof-errors are "ahcroödextrin," on p. 33, "cadmi'i," on p. 187, "horedeum," on p. 370, and "taraxa'cum," on p. 672. A few of the other words which we have found mispronounced (all of them can hardly be proof errors) are anæmic, diabetic, hydramides, paresis, phenic, tinnitus, umbilicus, unipolar, urethan, and all the French words with scarcely an exception. In the case of many words, the pronunciation of which is doubtful, we find no signs whatever to indicate their orthoepy, while in other simple English words such as acid, beak, croup, fossil, idiocy, scab, scald, toxic, typical, ulcer, wrist, the pronunciation is marked with absurd precision. Sometimes in a single word we find everything made clear except the one point on which there may be doubt. For example, on p. 583 we see the word "primi'tiæ," with the accent indicated as well as the quantity of each *i* carefully marked, but we are left to choose between ā, ī, and ē as the pronunciation of the diphthong, and between t, s, sh, and ts, as that of the *t*. Then again, the same word is marked differently as it appears in different places. Thus we find "chlor'ĭdum," on p. 134, "chlo'ridum," on p. 641, and "chloridum," on p. 735. Under "diabetes mellitus" we are left entirely in the dark as to the pronunciation of the second word, although it is one that is almost always wrongly accented by medical speakers.

The authors are not more happy in their definitions than in their orthoepy, as the following, taken at random, will show.

Articulo Mortis (Lat.). At the critical moment of death; applied to one who is moribund or at the point of dying.

Bromelia Ananas. Ananas; a West Indian tree (*sic*), bearing a familiar fruit, the pine-apple.

Pledget. A compress or small tent or lint-roll.

Hydræmia. Spanhæmia. Applied to an increased proportion of water in the blood. In another part of the book the word spanæmia is spelled correctly without the *h*.

Many important words are omitted, at least we have been unable to find them in their proper alphabetical places. Among these are arthrectomy, bow-legs, cascara sagrada, Glover's suture, gullet, head, ischias, lovage, and iodide of potassium. Under "Solution," we find Goad by's, Lugol's, Monsel's, Müller's, and others, but look in vain for Donovan's, Fehling's, Fowler's, Javelle's, Magendie's, Vlemingkx's, etc. Donovan's, Fehling's and Fowler's, we find elsewhere, but the others are wanting entirely.

But it is needless to search for any more faults in this dictionary. We have found enough, and they are glaring ones, to convince us that the work is not one that can be commended. Before and above all things, a dictionary maker must be accurate, painstaking, and plodding, and he must, moreover, have some knowledge of lexicography. We have failed to find evidences of any of these necessary qualities in the work before us.

There is an appendix. This may be good, but we have not had the courage to examine it.

Cure Radicale des Hernies. Avec une Étude Statistique de 275 Opérations et 50 Figures Intercalées dans le Texte. Par le Dr. Just Lucas-Championnière, Chirurgien de l'Hôpital Saint-Louis, Membre de la Société de Chirurgie, Président de la Société d'Obstétrique et de Gynécologie. Paris: Rueff & Cie. 1892.

The author of this work has written much, at one time and another, upon the subject of the radical cure of hernia, and has now collected in one large book these writings, and made of them a connected treatise. His method is to resect the hernial sac as high up as possible, in order to obliterate as nearly as may be the infundibuliform depression at the internal ring. This done, the tendency to rupture at this point is greatly lessened, if not removed entirely. Originally proposed for inguinal hernia, the method has been extended to femoral and umbilical herniæ as well. The author believes in the efficacy of his own operation, and does not waste any time or space in describing the methods of others. The work is not, therefore, a general treatise on the radical treatment of hernias, but is simply an exposition of Dr. Championnière's individual views and practice. The personal character thus imparted to it enhances in no small degree the pleasure of the reader.

Bacteriological Diagnosis: Tabular Aids for Use in Practical Work. By James Eisenberg, Ph.D., M.D., Vienna. Translated and augmented, with the permission of the Author, from the Second German Edition. By Norval H. Pierce, M.D. Philadelphia and London: The F. A. Davis Co. 1892.

This is undoubtedly a welcome work of its kind, being so practically arranged that its place will be found in every laboratory. It will also save time, for every investigator will have at a glance, alphabetically arranged, just those points most necessary for his bacteriological diagnosis. The translation will be of service to our American bacteriologists, and also to scholars.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, held at Nottingham, July 26, 27, 28, and 29, 1892.

SECTION OF MEDICINE.

FIRST DAY, WEDNESDAY, JULY 27TH.

Diseases of Plants.—DR. W. H. RANSOM, President of the Section, selected as the subject of his opening address "Some Diseases of Plants Compared with Those of Men." Inflammation in plants might, he said, have been the title of his paper, as it would deal almost solely with that process which, as he defined it provisionally, might be considered as the reaction of living cells to irritation. All such reactions in plants produced what were called galls, using the word widely, but some of them which occurred in growing points were known as witch-knots. It might be convenient to add that a gall should be considered as a local hyperplasia, or overgrowth of tissue, which differed from a local hypertrophy in that it diverged in structure and form from the normal tissue or organ with which it was related, and injured, or at least did not benefit, the plant. The irritation giving rise to galls might be mechanical, possibly; but, as a matter of fact, it was almost invariably found to reside in the secretions of some insect. In all instances local hyperplasiæ ensued, with modification of structure and form, and in each there was such a definite relation of the process to the irritant that the evolution of the gall was mainly directed by it, and the product was therefore specific. In the case of galls due to insects, the insect which laid the egg was usually spoken of as the cause of the gall; but, to speak accurately, it was only constantly associated with that cause, which directly inhered in the developing embryo in ovo, or in the young free larva. Some organisms, such as fungi, made no wound when they caused galls. The irritant was probably an organic chemical substance producing persistent disturbance of the metabolism of the living cells. The power of reaction to irritation resided in all the living cells, although most marked in the younger. Repair was not specific in relation to the cause of the injury, but in similar tissues was always the same. Those who accepted the view of inflammation would consider all inflammations specific, even when the phenomenon ascertained did not suffice to prove them to be so. From the purely clinical standpoint many inflammations would still be spoken of as simple or common; but, with the progress of etiological knowledge, the number of specific inflammations would increase at the expense of those which, from lack of knowledge, were called common. Something, he thought, would be gained to the science of pathology by its closer association with etiology, and then classification of diseases would be improved by an increase in the number of specific maladies.

Peripheral Neuritis.—DR. I. S. BRISTOWE, of London, opened a discussion upon this subject. He considered that it was now generally accepted that nervous disturbance was a cause of several diseases. Some poisor, developed either within or without the system, often caused such diseases of the nerves. Alcoholic peripheral neuritis was the best marked of all the forms of neuritis. He cited three cases. A lady, with ascites and cirrhosis, had mental symptoms at first, and then became numb on the fingers and toes. She got well. In the second case, a lady died with evident symptoms of peripheral neuritis. There was probably in her case paresis of the diaphragm. In the case of a man, aged thirty-three, who had been in the Indian army and was a great drinker, the power of reading the papers was lost, and the patient had tingling and numbness in the hands and toes. He had bilateral facial paralysis, could not smile, and had difficulty in swallowing. The pupils were equal, and reacted well to light. The muscles of the upper and lower extremities were weak. There was neither albumin nor sugar in his urine. The next group of cases he styled "hysterical neuritis." In the case of one woman there were attacks about twice yearly. There was tenderness in the fingers. She was stout and healthy looking. There was swelling and redness over the left forearm, and the limb felt cold. She was treated with arsenic and the continuous current. The arm was placed in a bath at blood heat, which was very successful treatment. She again returned to the hospital for the same affection. There was some slight wasting of the muscles of the forearm. In the case of another girl, aged twenty, there was swelling of both hands. A third case was that of a young lady of a highly neurotic stock, who lost the use of her lower extremities. The muscles of the forearm and hands were tender, and there was great anæsthesia of the lower limbs below the knees. She would have fallen if she closed her eyes. There was but little urine passed, about a pint in the twenty four hours. A lady, aged forty, took by mistake a lotion containing belladonna and opium. Neuritis of the arms developed after her poisoning, which had threatened to prove fatal. Here, then, were three classes of cases—alcoholic, hysterical, and a third kind of case, viz., one caused by the action of poison suddenly. He had merely given a few cases to show what had come before his own observation in certain well-defined circumstances.

DR. BYROM BRAMWELL said that perhaps no subject had for the last ten years led to greater discussion than this of neuritis. The most common form, alcoholic, was perhaps at present well made out. Hysterical neuritis was a new term. A complete recovery often took place. He had seen a number of cases which were rapidly cured, one of them being in a lady over eighty years of age. In some cases, however, the patient had died either of the disease or of some other complication. The toxic poisons which produced this neuritis were curious and were numerous.

DR. HANDFORD related a case of peripheral neuritis occurring in acute rheumatism. A girl of twenty years of age, with acute rheumatism, with profuse acrid sweats, had considerable swelling of both arms, there was loss of sensation in the left hand, which remained for some months. There was wasting of the muscles of the thumb and little finger. In another case there was pigmentation of the skin, and in another there was syphilis and alcoholic poisoning and sclerosis of the cord.

DR. PRYCE referred to neuritis occurring in diabetes. He knew of only two cases having been published of this form of neuritis. There was ataxia in some of these diabetic cases. In the case of a man, fifty-six years of age, with diabetes, with an alcoholic history, there was a perforating ulcer of the foot. The nerves of the leg were found by Dr. Byrom Bramwell to be much diseased. In another case, in a man aged sixty-two years, with diabetes and gangrene of the legs, there was no parallelism between the amount of sugar and the severity of the symptoms. In another case there was diabetes, ataxia, and gangrene. All of these cases were fatal.

DR. NEAL, of Nottingham, showed a patient with rheumatic neuritis, who had been ill for a year, and who exhibited great wasting of the muscles of the upper and lower extremities. He was now much better than he had been, and hence he thought the case was one of alcoholic neuritis, and not of progressive muscular atrophy.

DR. C. K. DRYSDALE, of London, said that in his experience there were several causes of peripheral neuritis, among which might be placed alcohol, syphilis, gout, rheumatism, diphtheria, phthisis, and leprosy. As to alcoholic neuritis, it had happened to himself to see more cases of the affection in men than in women, although the contrary opinion had been entertained by some authors. Alcoholic neuritis was often easily cured in a few months, if the patient could be kept without alcohol in a hospital. Hyperæsthesia and anæsthesia were often

well-marked in this form of neuritis, and the muscles of the upper and lower extremities became wasted and very tender when pressed. Syphilitic neuritis was often seen in young women with secondary syphilis, who exhibited anæsthesia over large areas of the body. Lead and copper poisoning and rheumatism were all well-marked causes of neuritis.

Dr. F. Taylor said that it was remarkable what a number of causes might be given for neuritis, some of which had been mentioned in the discussion. He asked whether exposure to cold might not, *per se*, be looked upon as a cause of the disease. In one case he had seen such had been the only explanation of the facial affection and other symptoms of peripheral neuritis. He meant to refer to the effect of cold, and not to allude to the possible existence of a rheumatic poison in the system. The patient he had described recovered completely. Although he admitted, with previous speakers, that many of the slighter cases of alcoholic neuritis quickly recovered, it must be confessed also that in other cases the disease was a very severe affair. Thus, in the case of a barmaid, which he had published, the patient developed great rigidity of the limbs, which continued in spite of treatment, and which eventually put an end to her existence. As to the comparative frequency of peripheral neuritis in men and women, he could not express any opinion. At all events, the affection was very frequently met with among males, and would doubtless be more frequently described now that the symptoms had been so well made out.

Dr. Pope, of Leicester, said that the case shown by Dr. Neal had a great resemblance to progressive muscular atrophy; but, as the patient had recovered greatly, and as there was absence of knee-jerk, he was inclined to look upon the case as one of multiple peripheral neuritis. The patient had had a relapse lately.

Dr. Freeland asked whether hyperæsthesia was common in alcoholic neuritis. Some patients he had seen suffered terribly, and the muscles of the calf were extremely sensitive.

Dr. Septimus Gibbon mentioned that he himself had had neuritis after a fall from a horse.

The President said we should speak of neuritis as a group of diseases.

Dr. Bristowe looked on hysteria as not connected with the higher nerve-centres only, for there were hysterical hip-joints and also hysterical peritonitis. Neuritis was curable in a very great number of cases. Sometimes patients with alcoholic neuritis remained affected for a year or longer. An alcoholic patient was much more likely to take neuritis from exposure to cold than others. He had no idea whether neuritis was commoner in men or in women. Syphilis was undoubtedly a common cause, and also exposure to cold. Sometimes there was no apparent cause. He looked upon hyperæsthesia as a very common symptom in neuritis, and tenderness of the muscles on pressure was a frequent symptom of this affection.

Second Day, Thursday, July 28th.

Ascites.—Dr. Cheadle, of London, opened a discussion on this subject. He said that, in the vast majority of cases, ascites was due to alcoholic cirrhosis or to syphilitic disease of the liver. Dr. Murchison had given a very bad prognosis in cases of cirrhosis. Dr. Fagge also gave a most gloomy prognosis. Dr. F. Roberts regarded cirrhosis as sometimes curable. Until 1884 the speaker had never seen a case recover. In spite of, and, perhaps, sometimes in consequence of, treatment, patients used to go on from bad to worse.' Thirty-six cases were spoken of in 1886, where recovery, more or less, took place. In 1884 he had a bad case of cirrhosis with much ascites. The patient recovered under frequent tappings and the administration of iodide of potassium. This case was syphilitic. Since that time he had quite altered his practice, and had had twenty-two cases of recovery. The cases did far better now than formerly. In all the cases where the patients quite recovered, the liver was large. When it is contracted there is very little hope. If only the liver remained of moderate size there was some hope, however much emaciation there might exist.

There was a distinction in the microscopic appearances between enlarged and contracted liver. The hypertrophic cases he thought would turn out to be syphilitic. In a case he had recently in St. Mary's Hospital, a man had hard liver and was getting quite well under large doses of iodide of potassium. There was a close connection between alcohol and syphilis. The alcoholic cases sometimes recovered. We might conclude that both alcoholic and syphilitic livers might be cured. So long as there was sufficient liver tissue remaining the patient might recover. As to treatment, abstention from alcohol should be strictly recommended. Good food and iron were useful. As to the mode of removal of the fluid, there was even now a dreary uniformity in books in the treatment. Diuretics, purges, and mercury were used. There had not yet been any change in the practice. Hydragogic purges, however, were most dangerous to the patient. As to diuretics, they were of very little use. Rosin of copaiba had been extolled; but he had been singularly unfortunate in his use of diuretics in all forms in the treatment of ascites.

Paracentesis was the only useful remedy. This was a most common sense procedure, and it was strange that it was not more used. It was the weight of authority contained in text-books doubtless that kept the old practice up. All the intestines suffered by the pressure from ascitic fluid. The fluid which did so much harm should be removed as early as possible. The operation was perfectly free from risk in almost all cases. If the patient were in anything like ordinary strength, there was no danger. Continuous drainage had been used in ascites. Repeated tappings were very useful, and only required ordinary care in attending to the purity of the instruments. Potassium iodide should be given in all cases, as in many syphilis existed. In ascites due to heart disease paracentesis was often useful. In tubercular peritonitis the effusion was not usually great, and did not often require tapping. Abdominal section was admirable in some instances.

Dr. Schroeter said that he agreed with Dr. Cheadle in his opinion that purges were of no use; but, as to diuretics, he could not quite agree. Calomel was of service, as also some other diuretics. He also argued that it was not well to wait too long before tapping He had himself treated sixty-nine cases of ascites, which were cured. He would begin the treatment with diuretine (theobromine-natro-salicylicum).

Professor Semmola, of Naples, said that the treatment and curability of ascites had in latter days been amply discussed. Twenty-four cases had been presented by him at the Congress of Amsterdam, thirteen years ago, cured simply by milk treatment. When a case of ascites occurred, it was not necessary to have recourse to tapping, or indeed to any drug treatment. There were a certain large number of cases where milk treatment succeeded in rapidly and completely removing the ascites. It was indicated in the early period of interstitial hepatitis. It used to be thought that ascites connected with cirrhosis was quite incurable, but this was an error. The speaker had recently published a work on this treatment, and Dr. Charcot had lately admitted the curability of cirrhosis in the early period. In mechanical obstruction the cases would prove fatal under drugs or under the milk treatment. Milk and iodide of potassium were the true remedies in curable cirrhosis.

Dr. West said that in severe cirrhosis of the liver a cure could not be expected. Free purgation was certainly hurtful. Diuretics sometimes were of service; at other times they were of no use at all. Especially was this true in great effusions in ascites. In chronic ascites

there might be a pressure of twenty millimetres of mercury in the abdomen. When ascites was cured, a collateral circulation always occurred in the abdomen. The treatment of ascites by rest was a very essential part of the principle. Another very important point was to see that the patient cut off the use of alcohol. If patients with cirrhosis were carefully treated, they might live a very long time. It was probable that large livers sometimes became small and atrophied. Hypertrophic cirrhosis was undoubtedly very rare in this country. Continuous drainage was not dangerous, in his experience, in the treatment of ascites.

Dr. S. Bristowe said he had read a paper about twenty years ago on this disease. He was still in favor of diuretics, in a very great proportion of cases. In many instances the cirrhosis of the liver seemed to improve. Rest in bed and tonics were the main points in treating ascites. The speaker was not in favor of opening the abdomen in tuberculous peritonitis. He confessed he could not remember any case where a big liver had become smaller.

Dr. Ratcliff presented some conclusions arrived at by himself and Dr. Wilson on the most frequent methods of collateral circulation. In books it was stated that the external abdominal and hæmorrhoidal veins carried on the circulation; but, in reality, he and Dr. Wilson found that there were many other routes taken by the blood. In very many cases the veins of the œsophagus were enlarged, and by this route the vein of the supra-renal capsule of the other side was reached. This gave great relief to the patient in many cases of ascites.

Another route was through the coronary vein of the stomach, which became greatly enlarged. The hæmorrhoidal route was, they found, the least frequently taken of all. Sappy's vein was sometimes very much enlarged. The external abdominal veins played an unimportant part. All cases of recovery from ascites must be accompanied by enlargement of such veins, and the stomach route was the most important of all.

Dr. Wilson remarked that the œsophageal route was the most dangerous of all which the collateral circulation could adopt, since in this case hæmatemesis was to be dreaded from the bursting of the large veins at the coronary end of the stomach.

Dr. Tooth said that many cases of ascites occurred in his experience for which no cause could be discovered.

Dr. Tyson said that the late Sir W. Gull had formerly recommended bitartrate of potash as a very useful remedy in ascites, and he had found it useful, as also iodide of potassium.

Dr. Drysdale of London, agreed that drastic purges were very bad in ascites, and that diuretics were of very little use. He relied almost entirely on warmth, rest, and frequent tappings; and that, with total abstention from alcohol, cured many cases of early cirrhosis.

Dr Cheadle, in closing, said that he was forced to conclude that there had been a remarkable agreement come to on the points concerning which he had spoken. He had not tried diuretine. Many cases of tubercular peritonitis doubtless recovered by rest and warmth. As to Dr. Tooth's cases, he thought these must be rarely met with, as the cause of ascites was usually discoverable.

Ice in Pericarditis.—Dr. Lees read a paper on the treatment of pericarditis by ice-bags. The great majority of cases, he said, of pericarditis arising in Bright's disease were fatal. Statistics would show that the heart was dilated and subsequently dropsy supervened. Forty years ago, venesection and mercury and opium were used. Nowadays a small blister or the application of a few leeches was all that was left. Many physicians did scarcely anything, and even less, for they withdrew salicylates in pericarditis. Some German physicians had tried the use of ice in such cases. In 1889 he had used ice-bags in pneumonia. In 1890 he tried ice in rheumatic pericarditis. In that case the pulse was 140, and respiration 60. He put a large ice-bag over the heart for twenty-four hours. This gave relief, and the pulse fell to 104. The salicine given was lessened in amount. In that case the ice did no harm. In a second case there was no rheumatism; but ice did much good, continued for four days. This patient had empyema of the right side, and died of this disease.

Tuberculous Broncho-pneumonia.—Dr. Gordon read a paper on this subject. He mentioned the case of a child who, shortly after an attack of measles, acquired a cough and became greatly emaciated. The pulse was 140, and diarrhœa was frequent. The diagnosis was broncho-pneumonia. This child died, and there was no tuberculosis apparent. There was no breaking down of the lung tissue. The lungs were hardened and examined, and he found in the cells thickening of the walls of the alveoli. This, then, was doubtless a case of acute tuberculosis, which assumed the form of acute catarrhal pneumonia in children.

Venesection.—Dr. West read a paper on blood-letting. The author said that free bleeding had been abandoned, and with great justice; but in some cases it was useful within moderate limits. Hemorrhage within the skull and in the lungs was usually fatal, and bleeding for hæmophyses must always be of doubtful utility. It used to be the practice to bleed in such cases. A patient, aged fifty-four, had fits of unilateral character and on the left side. Dr. West bled him to the extent of thirty ounces, and the patient was relieved. The severe fits gradually ceased. A man, aged forty-two, had sudden and unilateral fits, probably due to unilateral hemorrhage. He was bled and the fits ceased. In another group of cases the object was to afford relief to weakened vessels. A man who had suffocative catarrh was much relieved by venesection. In some cases of morbus cordis he had also found bleeding of service, for instance, when the right ventricle was enlarged. In pneumonia, bleeding used to be the routine treatment; and that was exploded; but the cases of pneumonia in which bleeding was useful were those where there was no great asthenia of the heart. Such cases were rare. In uræmia, bleeding had been recommended in order to get rid of poisoned blood; but the speaker had never seen any advantage from this practice.

Phthisis in Egypt.—Dr. Sandwith, of Cairo, read a paper on phthisis in that city. He spoke of four hundred cases of phthisis seen by himself, and the number of cases of improvement spoke well for the climate of Egypt. For early cases of phthisis Egypt was an excellent climate. One-fourth of the patients in a general hospital in Cairo were tuberculous. There were, however, many negroes among these patients. Phthisis was rare in the Soudan, which was a dry climate for the English; but for negroes it was a damp climate. The tubercle found in black patients was extremely infective in its character. Ulceration of the intestines was very common in the tubercular patients in Cairo. Altogether he considered the climate of Egypt as one likely to prove more serviceable to English patients in the early stages of consumption. In the later periods of the disease, he thought that consumptive patients were more likely to do well at home, and he narrated several cases where patients with large cavities had come to Egypt under the care of a medical practitioner, and who had speedily succumbed after the fatigues of the journey. It was to be hoped that they came of their own accord in such cases, and that they were not sent to die by medical advice. The climate was a most enjoyable one in winter.

Third Day, Friday, July 29th.

Treatment of Heart Disease.—Dr. Semmola, of Naples, read a paper on this subject. The author said that the results obtained by experiments on animals were of but little use in the treatment of heart disease. The most important indication in the treatment of such diseases was to be looked for in the etiology of each indi-

vidual case. The physicians attempted in valvular diseases of the heart to regularize the rhythm by means of tonics and digitalis; and in many such cases the influence of therapeutic remedies was extremely powerful, sometimes quite miraculous. But in other cases it was not the valves alone, but the whole heart that was diseased; and these constituted the most deplorable cases the physicians had to treat in practice. In such cases as these no light was obtainable, even from the best devised experiments on the lower animals. Such patients unfortunately almost always succumbed to the heart affection. What were the bio-chemical conditions of such cases? In the first place, all dyscrasias might affect the muscle of the heart as they did other tissues of the body. In one case he had met with, a man had dropsy and several other very severe symptoms of heart disease. He found that he had formerly suffered from syphilis, and consequently he treated him with specific remedies, and in four weeks the patient was restored to health. In some syphilitic patients with similar symptoms such treatment did not succeed; and in such cases the speaker was in the habit of making a microscopic examination of the patient's blood, to ascertain the amount of blood-corpuscles in it. He had had seven cases of heart disease which had been cured by this specific treatment. Myocarditis, when syphilitic in its causation, might often be cured.

Dr. Drysdale, of London, mentioned the case of a distinguished medical man, since deceased, who had myocarditis of the nature of the cases mentioned by Professor Semmola, and was benefited by iodide of potassium.

Sir F. Bateman, of Norwich, said he could corroborate the view that myocarditis was sometimes due to syphilis. He complimented Professor Semmola on the way in which he had worked out the history of such cases.

Dr. J. Lavies said he was not quite able to agree with Professor Semmola that experiments on animals were useless in heart disease. He had tried the treatment by specifics in some cases of myocarditis, but he must say with little benefit in most cases. Nowadays diet and exercise were more used than drugs in the treatment of most cases of heart disease. He doubted whether in obscure cases it would be of service to use such heroic treatment of myocarditis as that favored by the author of the paper.

Gout.—Dr. Emil Pfeiffer, of Wiesbaden, read a paper on uric acid secretion in gout. He observed that the process for ascertaining the correct amount of uric acid in urine was now greatly improved. In gouty persons he found that there was diminution in excretion of uric acid while the attacks were acute; but in chronic gout the excretion was increased. Also, in disease of the kidney he had found increased excretion of uric acid, and this was quite contrary to Dr. Garrod's assertion. The hydrochloric acid process was not quite accurate enough. The observation of Garrod had made it be supposed that retention of uric acid was the cause of the symptoms of uræmia, but the result of his own numerous experiments with this more accurate method of examination for uric acid showed that this was not correct.

Perimeter Measurements in the Diagnosis of Local Brain Disease.—Dr. Byrom Bramwell, of Edinburgh, read a paper on the value of these measurements. The value of the perimeter in such cases was as yet not recognized by physicians. Dr. H. Jackson's advice, to examine carefully for optic neuritis, was not attended to for a long time after it was given. Everyone knew the great difficulty of interpreting experiments, even on monkeys, and this made the careful physician by far the best interpreter of physiological changes in the brain. At the tip of the occipital lobe in man there was probably a visual centre, any lesion of which caused hæmianopsia as its commonest symptom. There was also in such cases hæmiopic pupil. He related the case of a woman, aged fifty five, who had suffered from marked mitral stenosis. Two months previous she had become suddenly unconscious, and had remained in bed for a fortnight without being conscious of her condition. The only symptom observed in her case was homonymous hæmianopsia.

The patient died. The diagnosis made was that she had some disease of the left occipital lobe, and this was correct. There was infarction of the right side of both retinæ observed in this case. After death it was found that there existed a lesion at the tip of the left occipital lobe. This case showed well the great importance of perimetric observations.

An Epidemic of Cholera.—Surgeon-Colonel R. Harvey read a paper on an epidemic of cholera at Srinagar. This was seated in a valley of the Himalayas, and the town was five thousand feet above the level of the sea. In 1843 twenty thousand persons died of cholera. Severe epidemics went on increasing. Cholera germs required a suitable soil. Efficient quarantine for this disease was impossible. The true prevention lay in care for sanitary conditions. The history of cholera in England showed this well. The filth and squalor of the people in Cashmere was quite undescribably terrible. The natives cared nothing for either pure water, air, or for cleanliness. Their courtyards were used for defecation, and were horrible. The water of the river was like that of a common sewer. In 1888 it was that cholera was imported, and once introduced the disease spread like wildfire. In a town of one hundred and twenty-four thousand people there were two hundred and ninety-eight deaths in one day. The mortality in London's last epidemic was about three hundred a week, but as many as that died in a day in Srinagar. The epidemic was most terribly malignant, and sixty-five per cent. of those attacked perished, starvation ensued, for no kind of business was carried on. The advice to drink boiled water was disregarded, as being an interference with Providence. The European community lived in a quarter by themselves. They left the city, much to their own advantage. Cashmere was an independent state, and the European resident had no power. In the fourth week of the epidemic, in 1892, there were one thousand eight hundred and three deaths out of two thousand five hundred and seven cases of cholera He had recommended pure water to be brought into the city by pipes, and this would probably be attended to, since another city of Cashmere had been thus supplied, and thus cholera had been kept away from that city.

Dr. Coghill, of Ventnor, said that when he lived in China he found the filth there to be even worse than it was described to be in Cashmere. He proposed that the recommendations of Dr. Harvey be forwarded to the Council. Surgeon-Major Cornish seconded this resolution, and referred to the coming invasion of cholera. Probably the cholera would arrive in England; but he believed that we might look on with a certain degree of tranquillity, since we had good water and good drainage.

Some Complications and Sequelæ of Infectious Fevers.—Dr. Francis Hawkins read a paper with this title. He cited some French authors who had described endocarditis as occurring in scarlatina. He had lately been trying to study this point to see what was the state of the heart in the exanthemata. To commence with scarlatina, he had never heard a pericardial friction in uncomplicated scarlatina. When the disease was complicated with rheumatism, he had had four cases. After death he had found adherent pericardium and a slight affection of the valves. In 100 uncomplicated cases of scarlatina, in 4 there was a passing murmur heard. Pericarditis had been said frequently to occur in this disease, but of 650 such cases only one was due to scarlet fever. Scarlet fever complicated with nephritis showed occasionally pericarditis. In diphtheria, and in measles also, murmurs were observed, which lasted a short time and disappeared.

Neuroses in Chronic Rheumatoid Arthritis. — Dr. Hugh Lane read a paper on this subject. There were, he said, two affections which were often confounded, viz., rheumatic arthritis and rheumatoid or strumous arthritis. His remarks merely applied to the latter. There was great loss of appetite often noticed in such cases. This mal-assimilation of food caused emaciation. There was rapid pulse, 120 to 150 in some cases, hard in character. There was high tension observed in the sphygmographic tracings. Nervous symptoms were well marked, and might be general or local. In younger persons the history of phthisis was common. Local sweating was noticed in the course of some nerve. There was paralysis of the vaso-motor muscles, as shown by the rapid pulse. Purpuric eruptions were commonly noticed. Muscular atrophy was also frequently observed. The intercostal and temporal muscles wasted. It was not clear why there should be such wasting. The reflexes were not increased in rheumatoid arthritis, as had been said.

Association of Sensory Disorders with Visceral Disease.—Dr. J. Mackenzie read a paper with this title. The author had remarked that pain existed at the umbilicus when there was some disease of the large intestine. A band of anæsthesia extended over the left ribs in the case of disease of the stomach. In the case of retained scybala he noticed there was hyperæsthesia down the buttocks and back of the thighs. In disease of the spinal cord the inside of the right arm and outside of the left arm had been noticed to be painful. In angina pectoris there was noticed pain over the heart and over the outside of the left arm. In diaphragmatic pleurisy the pain was noted in the supra-spinous fossa and on the left ribs, a little above the level of the umbilicus.

SECTION ON PUBLIC HEALTH.

Sir W. Foster, as Chairman of the Section, delivered the customary address.

Factory Operatives and Child-bearing.—Dr. George Reid introduced the subject of legal restraint upon the employment of women in factories shortly before and after childbirth. The speaker had obtained an important series of statistics bearing on the subject. He had found that in districts where women were largely employed in factories, the infant death-rate is greatly in excess of those where they are not so employed, in the proportion of 182 to 158. In those towns where women are most employed, the deaths of children under one year numbered 195 per 1,000, falling to 152 in those where practically no women worked in factories. In other words, twenty-eight per cent. more infants die in one case than in the other. The fact that the mothers return to factory-work a month after confinement, and are thus prevented from suckling their children, explains this excessive mortality, and Dr. Reid suggested that they should be forbidden by the legislature to return to factory-work for three months, so as to give the children a start with the natural food.

Cerebro-spinal Meningitis.—Dr. Monk described an epidemic of cerebro spinal meningitis which had occurred in Shropshire, the origin of which was traced to a school in which nearly all the scholars had, a few weeks previously, been attacked with diarrhœa. After the school had been closed and thorough disinfection carried out, no fresh cases occurred.

Disposal of Town Refuse.—Dr John W. Mason then brought forward the subject of the "Disposal of Town Refuse." He advocated the erection of furnaces in sufficient numbers to cremate at once all the refuse which could not be utilized for manure.

Prevention of Phthisis.—Dr. C. R. Drysdale read a paper on the prevention of phthisis and syphilis. He had been convinced by Villemin's experiments, in 1876, of the contagiousness of phthisis, and held that every fact since accumulated only confirmed the conviction.

He urged upon those who might be sceptical on this point that, in the face of so many facts as have lately been brought forward, it would be far wiser to act upon the hypothesis that phthisis is contagious than to do nothing. A disease which carries off a fourth or a third part of the population of some communities surely deserves more attention from hygienists that it has hitherto obtained. Are there any practicable means by which the contagion of phthisis can be prevented?

The speaker thought that there were. Segregation of patients should, if possible, be carried out. Hospitals for consumption should no longer be constructed in the midst of cities, where so few cures can be expected to be made. They should be built at the seaside, or on the slopes of mountain or hill ranges, wherever these are accessible. Healthy persons should not occupy the same couch with the phthisical, and the sputum of consumptive patients should be destroyed as soon as possible. The walls of their hospitals and the floors should be frequently washed, etc.; there should be no carpet.

With regard to contagium from the lower animals, that cause of phthisis, although not for one moment to be compared in frequency with that derived from human intercourse, is yet of very great importance. All animals used either for the purposes of milk or meat supply should be carefully inspected, and they should at once be destroyed if they exhibit signs of tuberculosis. The food-supply would not be lessened by these methods, which would simply have the effect of causing cattle-dealers to be more alive to their own interests, and therefore more attentive to the hygiene of their animals. There is no need that there should be any tuberculous disease among cattle, which, under good circumstances, remain entirely free from such disease.

Prevention of Syphilis.—The speaker then turned to the question of syphilis, and said that it was very difficult to understand why civilized nations have as yet done so little to prevent this disease. The only reason Dr. Drysdale could assign for this was that it seems to have been thought that syphilis is not like other diseases, but that it is inflicted upon mankind as a punishment for some sin. At the first blush, it would appear that, of all diseases, syphilis is one that should be most easily prevented. It possesses a fixed virus, and is only communicated by contact or by heredity. It never appears *de novo*, and the contamination is rendered more difficult because it is necessary that the virus shall penetrate through a fissure of the mucous membrane or of the skin. Everyone knows that the contagium of syphilis is neither influenced by bad hygienic conditions nor by atmospheric variations, nor again by the nature of the soil or habitations. Danger resides solely in the diseased individual. It is then perfectly clear that, if all persons affected with syphilis could be separated from the rest of the world during their contagious period, the disease would be banished from the community. But, of course, nothing in that direction has ever been tried. The only plan that has met with any favor on the Continent of Europe has been the system of examination and registration, first made use of in Paris.

In 1867, when the question was discussed under the presidency of M. Ricord, Dr. Drysdale stated, and now he repeated, that after having carefully examined the question in London and in Paris, he came to the conclusion that Paris had a greater spread of contagium than London, although the latter city had no such system of examination. The writings of MM. Lecour, Lefort, and Jeannel, have abundantly shown that the French system, in addition to being extremely unfair to all women, is almost useless in preventing syphilis. Belgium has long been renowned for the strict way in which the French system has been carried out, and Professor Crocq and the late M. Vleminck, in company with Professor Thiry, have always been eloquent as to the advantages accruing to the Belgian army from the strict carrying out of the system. On several occasions he (Dr. Drysdale) had to express doubts as to the correctness of the statements of

these gentlemen, and last year Dr. Moeller, in a paper read at Brussels (October 5, 1891), conclusively showed by statistics that in the Belgium garrisons the diminution of venereal diseases was greater in towns not fully under police regulations, than it was in towns under the regulations. It appears that the two garrisons which showed the most considerable diminution in these diseases are those of Beverloo and Diest: the first presenting the enormous diminution of four hundred and twelve per thousand, and the other sixty per thousand. Whereas in Antwerp and other towns under complete police regulation, the diminution was from thirteen to four per thousand. The same fact has been shown in Hindoostan and also in England.

The first practicable measure for preventing the spread of syphilis is fuller instruction in the pathology of the disease, so that medical men may be at once able to recognize it. This teaching has hitherto been neglected; but the post-graduate courses now in fashion should easily remedy that deficiency. When the patient appears before the medical adviser, the latter should consider it as his solemn duty to inform him or her of the nature of the disease and its contagious character, and of the dangers that may arise to other persons from any close relations between them and the patient. The law admits of the prosecution of anyone who, conscious of his own disease, communicates it to another; but unfortunately this law is seldom put in force. All women and men who are known to have spread the contagion, in spite of being warned, should be liable to a period of enforced seclusion or imprisonment, as it is evidently a criminal act wantonly to spread contagion. In cases where syphilis is communicated without the knowledge of the infecting person, an action for damages lies against the person who has given the disease; although such cases rarely come before the courts, except when an accoucheur communicates the disease in the exercise of his art, or when the parents of syphilitic children are occasionally sued for damages by the foster-mother of the infant. As in the case of all other crimes and injuries, the true way of preventing syphilis is by punishing as a felony a criminal action against the health of anyone. One important point to be considered is whether phthisis and syphilis should be placed in the category of notifiable diseases. Sooner or later this will be found necessary. Civilized human beings will not consent much longer to submit to the attacks of such abominable contagions merely for the purpose of covering up the existence of such evils from the gaze of sentimentalists. There are, of course, difficulties in the way; but what is the use of intelligence if it is too supine to struggle against difficulties. Syphilis can and must be stamped out; and phthisis, it is to be hoped, will become far rarer when it is attacked by such preventive measures.

Conditions Under which Foreigners May Practise Medicine in England.—It is stated in the *Lancet* that a memorandum has lately been prepared, by direction of the General Medical Council, showing the conditions under which foreign medical practitioners are allowed to practise in England, as determined by the Medical Acts of 1858 and 1886. Foreign practitioners, though they cannot register or hold appointments, can practise in England without restriction so long as they use no name or title implying their registration. Hospitals established for foreigners may be attended by foreign practitioners entitled to practise in their own country and not engaged in other medical practice. The Act of 1886 goes further. In it provision is made for reciprocity in the recognition of foreign degrees at the instance of the Privy Council, and subject to the approval of them by the Medical Council as furnishing a sufficient guarantee of the possession of the requisite knowledge and skill for the efficient practice of medicine, surgery, and midwifery. The holders of such degrees are entitled to registration in the colonial or foreign register.

Correspondence.

THE HEALTH RESORTS OF THE RIVIERA.

(Continued from p. 229.)

X.—Bordighera and Ospedaletti.

(From our Special Commissioner.)

Bordighera, March, 1892.

We are in Italy now. But no sudden transition marks the change of territory. In fact, from Nice eastward, and including that lively city, the native population, the character of the old buildings, the look of the land, and the patois dialect of the common people, all point unmistakably to their Italian origin. It has been aptly said that Napoleon made Nice, and her eastern neighbors France, but God had made them Italy. And whether on French or Italian soil, the general features of these Riviera resorts remain the same. What was taken by France from Italy may be some day restored. But the Riviera will always retain its sunshine, and its shores will ever be laved by the waves of the Mediterranean, no matter what political alterations the powers may make in the map of Europe.

It has occurred to me that, having taken certain liberties with the various regions, divisions, or ports of the Riviera, as traditionally classified, arranged, and minutely described, I ought to explain the *raison d'être* of so appalling an American innovation. It is simple enough. I wished to avoid confusion. Accordingly, I bunched all the leading Rivieras, as found in the standard works, and then simply split them in two by taking the Franco-Italian boundary as my dividing line. East of that line you have Italy, hence the Italian or eastern Riviera, and west of it lies France, with the western or French Riviera. For completeness' sake, and because it sounds well, I threw in the Riviera di Ponente and Riviera di Levante, the former being used by the Italians for the littoral east of Genoa, and the latter for the coast to the west of that city, the whole region being spoken of as the Ligurian or Genoese Riviera. Those pedantic sticklers who insist on following in the footsteps of their predecessors may, therefore, continue to revel in an eastern French Riviera, a western ditto, an eastern Italian Riviera, a western ditto, a Riviera di Ponente restricted to the region east of Genoa, and a Riviera di Levante, ending as far west as possible, say at Toulon. Of course, the Rivière occidentale and orientale are merely the French terms for eastern and western Riviera. Now I boldly challenge the European "qualified person" to do better than I have done in this touchy matter, which, I trust, will not embroil the nations into serious disputes. It has always seemed to me a dazzling imposition that American citizens should have no other voice in European affairs than that small still cry of painful discomfiture invariably heard when the spread-eagler realizes, around bill-time, that he has spent many more dollars than he ought to have spent, or than a native would have been asked to have spent. If I shall succeed in persuading Europe to correct, up to the American standard of simplicity, her complicated and obsolete

system of Riviera geography, I shall confidently expect to receive all the latest improved orders and decorations, that look so well on manly breasts, especially while dancing the german at "at home" functions. Function, be it remembered, is not physiologically connected with bodily organs in this country. It means merely any sort of alleged entertainment. By an oddly contrived paradox, most functions here suggest interesting chapters on anatomy rather than physiology to the purely medical mind. Perhaps it is all on account of the climate, otherwise I should not have mentioned it.

Bordighera must take its place among the comparatively new health resorts that are constantly springing up along the Riviera. But Bordighera is a station which has evidently come to stay. Its winter colony consists at present chiefly of English and German residents. Americans, it would seem, have yet to discover the town.

Bordighera has long been noted for the great number and unexcelled beauty of its palms. In the most protected gardens the dates actually ripen on the stem in the open air, a very rare occurrence elsewhere on the Riviera. The natives also enjoy the proud privilege of supplying St. Peter's at Rome with the graceful twigs distributed on Palm Sunday. Indeed, the luxuriant growth of the many palm plantations lends an oriental charm to all the landscape at this point. Dean Alford says that there are more palms in this neighborhood than in the whole of Palestine. Apart from their commercial value to the natives, and in addition to their attractive appearance, they are also useful in supplying shady promenades when the sun's heat grows intense. Many fine specimens of lemon and orange trees are also found in the groves and gardens of Bordighera.

The name of the place is said to be derived from *bordigue*, meaning a creek. Owing to this creek the inhabitants are supposed to have found enough shelter to allow them to become expert sailors and fishermen any number of centuries ago. The old harbor has long since been destroyed by deposits of silt, but the natives still indulge in a poor sort of fishery, and peddle out their meagre catches to the Mentonese and San Remose markets. It is certainly interesting to note that the fishermen in many places along the Mediterranean littoral employ a jargon which includes words of evident Greek origin, and must date back to the time of the Phocæan occupation. But beyond this profoundly etymological hint I have no present intention of departing from the main subject.

Those who are fond of rural life, quietude, picturesque views, fairly good hotel accommodations, and varied botanical pursuits in a warm southern climate, and in a well-sheltered district, will find at Bordighera an eminently satisfactory winter station. But he who needs the stimulus of convivial gayeties must not tarry there. Hopeless *ennui* would speedily claim him for a victim.

Bordighera is the most western health resort of the Italian Riviera. It is only about three miles from the Italian frontier station of Ventimiglia. It is ten miles east of Mentone, and less than seven miles west of San Remo. Ruffini's well-known romance, entitled "Doctor Antonio," has made the old Bordighera familiar to readers of novels.

The old town is quite separated from the new residential quarters. It is quaint and dirty, has narrow streets, with strange-looking arches and queer buttresses, that are supposed to weld the houses together in such a way as to resist the dreaded power of earthquakes. As a matter of fact, the last earthquake created sad havoc in all these buttressed towns. Some little villages (*e.g.* Bussana, near San Remo) have indeed never recovered, and remain destroyed and deserted.

The Ligurian natives here, as elsewhere, have a knack of forming artistic groups against the odd background of ancient alleys and dark streets, so that it is not surprising to find the amateur sketch and water-color fiend out in full force. He is generally a girl, too, and often looks severely spinsteroid. Sometimes he is in couples, one moiety wiggling the dauber, while the other half makes frantic efforts to keep from wiggling that part of the foreground consisting of dirty and ragged humanity. I think the natives get as much fun out of the amateur artists as *vice versa*. But I do not think the artists think so.

At any rate, the old town, perched so picturesquely on the gentle slope of a hill, and showing remains of its ancient castellated wall, now crumbling away, and from the crevices of whose ruined battlements many wild flowers creep; the glorious mountain panorama to the west; the curving beach, dotted with fishing boats and spread with queer tackle to the east; landward the sea of green gray olive-trees; and to the south our old friend, the real sea, with the sunbeams dancing over the glittering expanse of turquoise, produced a profound impression on my retina. Yet I heroically refrained from sketching, though I must confess to an occasional pressure on the button of my Kodak.

They call the old town the *Borgo*, or Bordighera *ai sopra*, and the newer sections stupidly constructed in the much-exposed plain skirting the beach, the *Marina*. But the real residential quarter of New Bordighera now extends in a northwesterly direction from the latter, *i.e.*, along the *Strada Romana*. This position has been wisely chosen. And it may be remarked here that Dr. Sparks's description of Bordighera[1] does not fit this, the present and future home of the foreign colony. Indeed, as compared with other chapters of this author's carefully prepared volume, his study of Bordighera is an unsatisfactory production, although it is often quoted in the newest publications on the Riviera.

Bordighera's permanent inhabitants number less than three thousand. And the winter colony can be readily counted in the hundreds. Accordingly prices there are lower than at neighboring San Remo, or than at Nice, Cannes, and Mentone. Titled persons and representatives of American wealth-rollers have not yet spoiled the place for simpler folk, who at present are permitted to flock by themselves in this unpretentious resort. How long will this idyllic state last? The visit of one crowned head would spoil its charm forever. The natives are obliging and well disposed toward foreigners, whom they have not yet learned to regard as their legitimate prey.

Bordighera is without doubt a favored spot, and to me it is a matter of surprise that a real boom has not yet struck the place. Of course its climate is that of the Riviera in general. Yet it is so situated that you can really find three climates there, within the radius of a few miles. This feature will be searched for in vain in all the publications touching the place.

Readers of the RECORD may, therefore, thank both Dr. Goodchild, my informant, and myself, who was able to verify his claims, for giving them three climates, where less favored mortals escape with one.

Bordighera is situated on a broad tongue of land, the promontory of Sant'Ampeglio, which runs some distance out to sea. But it is not on a narrow promontory like the Cap d'Antibes or Cap Martin. Moreover, most of the newer hotels, such as the Belvedere and Angst, are inland in a westerly direction from the old town. They lie completely sheltered from the worst winter wind here, which blows from the east. The sunny exposure of this, the future residential quarter, makes it an extremely desirable neighborhood. Here you have really a modified inland climate, for the salt sea-breezes prevailing at the Marina are considerably toned down before they reach it. Further up on the hillsides, thickly covered with the ever-present olive-tree, you begin to get a veritable mountain climate, whereas the true marine character of the climate is found only in the section adjoining the sea and near the cape of Bordighera. Naturally you can select combinations of these different climates, as they all blend at various points. In addition to this, it must not, of course, be supposed that the three zones are quite as distinct and

[1] The Riviera, p. 312. London: J. & A. Churchill, 1879.

separate in character as if they were situated in different degrees of latitude and longitude. But there certainly are appreciable differences.

Mr. Hamilton, in his exhaustive work on Bordighera,[1] says that the distinctive feature of the place is found in its large proportion of sea-winds and salty air, which gives the climate an essentially tonic character. But only the older portions of the settlement are fully exposed to these warm, damp sea-winds, and the description does not fit the newer sections.

Dr. J. A. Goodchild is the only English physician permanently residing here. He has spent fifteen winters at Bordighera, and tells me that he has not had reason to modify his earlier impressions as quoted by Mr. Hamilton. I cannot do better than borrow some of the more important points to which he has drawn attention, more particularly as he impresses one as a fair critic and observer, rather than a blindly optimistic local enthusiast.

The average temperature of Bordighera in the winter is much the same as that of its neighbors. But it is cooler in spring and autumn, and warmer in midwinter than most of them. The east bay of Mentone is undoubtedly the warmest situation on the entire coast, and yet, while the maxima at Mentone are usually from four to six degrees higher than at Bordighera, the minima are in almost every instance lower. The explanation consists in the fact that radiation goes on far less rapidly during the night from the surface of the densely sheltered plain and hills of Bordighera than from the bare and rocky mountains which form the coast at Mentone. Two other causes contribute to render Bordighera more suitable for those who wish to be much in the open air in mid-winter than either Mentone or San Remo. Both are due to its southwestern aspects, the two latter places facing southeast. The first is, that the sun sets into the sea so that its warmth is preserved till the last moment, while at Mentone and San Remo it sets nearly an hour earlier behind the mountains which lie to the west of these places. This is a matter of great concern to invalids in the short winter, as the afternoon is thus considerably prolonged, and the sunset chill comes on more gradually.

The second advantage consists in the much fuller protection which Bordighera enjoys from the east and southeast winds than its rivals. These are the prevalent winds there in mid-winter, and blow straight into the neighboring towns.

As regards humidity, Dr. Goodchild says that, while the average moisture is very low, the dryness does not equal that of Cannes. The changes from saturation to extreme dryness are also less rapid, owing to a richer soil and the abundance of trees. This is not without advantage, especially to newly arrived invalids, who have not been previously acclimatized. Hamilton places the general mean of moisture for the winter months at 64.

The shelter vouchsafed to New Bordighera is due to a series of unbroken hills from five hundred to one thousand feet high, that rise up about half a mile from the coast and intercept the east and northeast winds, and even to some extent the southeasterly breezes. Violent north winds can scarcely strike the place, and the northwest winds are also diverted away from it by the distant Maritime Alps. The *mistral* is still felt at times as a westerly wind, but it is robbed of the power that makes it a terror at Hyères, Cannes, and Nice. When it does blow it always brings fine weather in its wake. Bordighera is fully exposed to southwesterly breezes, but these only rarely blow with the force of a gale (vide later). The rectangular cape cuts off the edge of the really bad winds here, namely, the easterly winds. I wish to repeat, however, that I am writing of "New Bordighera" only, and not even the Marina, which is also of comparatively recent origin. Of course, currents of cold air come down the gaps in the mountains, but this is an objectionable peculiarity that no part of the Riviera is entirely exempt from.

[1] London: Edward Stanford, 1883.

When the southwest wind does attain the force of a gale lasting several days, they give it all sorts of bad names, and it then feels called upon to change its tactics by drenching the landscape in tropical rain. This diverts attention from its breeziness, and earns for it the name of *libeccio*, a liquid Italian designation for what we would simply call a snorter. They name some things better in Italy than in our country.

From some slight experience here, I am inclined to agree with Mr. Hamilton, who divides the easterly winds into two classes. In fact, if I had my way I should prefer to divide them into twenty classes, for equal distribution among twenty enemies. The east wind is never a pleasant wind. No. 1, the true Italian *levante*, is a wet wind blowing from over the marshy plains of Tuscany. Hamilton says that it is originally a *sirocco*, deflected from its southeasterly course by the chain of the Apennines. According to his observations it is the wind which not only brings the worst weather, but it also has the longest duration. No. 2, the other easterly wind, is not accompanied by wet weather. It is merely a cold Genoese *stramontana* drawn to the west by the sun's action on this part of the coast. It might be called an easterly mistral, so analogous in its origin is it to its western confrère. Like the genuine article, it is biting cold and strong. It blows furiously beneath a perfectly cloudless sky for hours or days. But, bad as it is, it does not altogether equal in malignant dustiness a true mistral.

I have dwelt on these winds because they have dwelt on me, and, while I consider Bordighera a sheltered place, at least for the Riviera, I wish to warn my countrymen against over-zealous partisans whom the Bordighera breezes have apparently never touched. It only hurts a place to circulate falsely optimistic views concerning it, views that a single visit will readily upset.

Observations on rainfall have only been made since 1879 at Bordighera. Mr. Hamilton places the averages yearly at about twenty-nine inches. Genoa is put down for fifty-two inches, Nice thirty-two, and Hyères about twenty-nine inches. Long-continued drizzles are rare, but violent showers are often observed. Snow is seldom seen, and never remains long on the ground after falling. The number of perfectly cloudless days is large at Bordighera. But I am afraid Mr. Hamilton must be set down as a zealous partisan when he gives the mean for Nice during the six winter months as 60, while crediting Bordighera with 80 absolutely clear days. Mr. Hamilton gives these details:

Perfectly Clear Days at Bordighera.

October	10.0
November	16.0
December	16.7
January	14.2
February	12.0
March	12.7
Total	81.6

Mean per month, 13.6, or about forty-five per cent. of the 182 days comprising the winter season.

Days Entirely Overcast at Bordighera.

October	4.7
November	5.0
December	3.5
January	5.0
February	4.9
March	2.7
Total	25.8

Mean per month, 4.3, which amounts to 7.8 per cent. for the season.

There is no system of drainage at Bordighera. The hotels and villas are provided with cesspools, that in most cases are placed at a sufficient distance from the residences to be only slightly obnoxious. Every cesspool ought to be properly ventilated, thoroughly cleansed when emptied, and always kept in good repair if cemented.

These obvious rules receive an added importance here from the fact that there is no general water supply, and that the character of the soil is such as to greatly facilitate ground filtration. I am not in a position to state that all these precautions are taken. But it is at least satisfactory to know that most of the establishments have English closets.

Water that residents are supposed to drink here is drawn from wells, and every hotel appears to have its individual supply. Some mountain-springs are also used for this purpose, but, so far as I have been able to ascertain the truth, it must be confessed that the potable water now in use at Bordighera cannot be safely recommended.

I understand, however, that negotiations are already under way to obtain a supply of the excellent Argallo water used at San Remo and Ospedaletti, the water to be conveyed as in the case of the places named, that is to say, by means of a completely closed aqueduct.

The only analysis of Bordighera water which I was able to obtain is one given by Hamilton, and refers to the springs of *Giunchetto*, near the *Madonna della Ruoto*. It is as follows: In one hundred parts of Bordighera water there are

Sulphite of calcium	0.03
Chloride of calcium	0.01
Chloride of sodium	0.04
Sulpho-carbonate of lime	0.03

The vital statistics of Bordighera show that it is a healthy place. The porous nature of the soil seems at present to still counteract the evils that may result from the absence of drainage precautions. The annual death-rate per mille is from twenty-two to twenty-three. This is satisfactory for the indigenous part of the population.

Dr. Goodchild informs me that the same absence of zymotic disease already mentioned in connection with other Riviera resorts is also a noticeable feature at Bordighera. Some years ago he observed some cases of a mild variety of measles, but as a rule he passes the entire winter without encountering an instance of any of the common contagious affections. Typhoid fever appears to be unknown here, which is more than can be said of some other Riviera resorts.

There are some fifty furnished villas now to be had at reasonable rates for the winter, and their number is annually increasing. Of the well-situated hotels the Belvedere, Angst, Londres, and Westminster may be mentioned. Fairly good stores, a bank, telegraph office, markets, and other conveniences essential to housekeeping are found in the new town, or village, as they prefer to call the place, in contradistinction to more ambitious neighbors.

Barring the inevitable English tennis-club, out-door life is restricted to walks and drives. New roads have been constructed and the old ones are being modernized. There is plenty of opportunity for pleasant rambles, and all about here there are really many bits of fine scenery that are well calculated to kindle enthusiastic admiration. In the words of Ruffini: Here you have in a small compass, refreshing to behold, every shade of green that can gladden the eye, from the pale gray olive to the dark-foliaged cypress, of which one, ever and anon, an isolated sentinel, shoots forth high above the rest. Turfs of feathery palms, their heads tipped by the sun, the lower part in shade, spread their broad branches, like warriors' crests. On the hill the slender silhouette of the towering church-spire cuts sharply against the spotless sky. Golden atoms are floating in the translucent air, and a halo of mother-of-pearl color hangs over the clear outlines of the mountains.

It is in the undisturbed possession of such natural attractions that the distinctive peculiarities of Bordighera are at present found, and not in the existence of a climate totally different from, and far superior to, that of other Riviera stations. And I may remark, in taking leave of this pretty place, whose white villas glisten in the far distance, that Dr. Onimus, usually so exact in his descriptions, has evidently failed to render justice to Bordighera.[1] He classes it with Vintimiglia, a town which certainly has no future as a winter health-resort.

Bordighera is claimed to be less stimulating and exciting than Nice or Cannes, but more bracing and less enervating than Mentone, resembling in these particulars its near neighbors, Ospedaletti and San Remo. Dr. Goodchild finds it an exceptional residence for almost any case marked by chronic degenerative tissue-changes. "Chronic bronchitis, asthma dependent upon the former disorder or upon disordered digestion, phthisis of a non-febrile type, exhaustion from over-work, nervous debility (neurasthenia), anæmia, chronic Bright's disease, chronic rheumatism, gout, and the varied forms of long-continued disease which affect mucous membranes, are all likely to derive more or less benefit from a winter's residence at Bordighera." Diabetes also seems to do particularly well at this Italian health-resort. Hæmoptysis furnishes a contra-indication. Acute hysteria, and all cases with a tendency to maniacal excitement, ought to be kept away from there.

If Bordighera is new, Ospedaletti is more so. If the former is small, quiet, and gratefully rural, the latter is diminutive, still as a spiked gun, and nothing if not intensely bucolic. Situated within easy walking distance of, and about midway between, two important health-resorts, viz., Bordighera and San Remo, there does not at first sight appear to be any *raison d'être* for its existence as a growing winter station. Nevertheless, and although it owes its present appearance to misplaced speculation, there is little doubt that its pretensions to rank as a sanitary resort are based on a really privileged position and decidedly agreeable surroundings.

According to Ruffini, a ship belonging to the Knights of Rhodes, while on a cruise in the Mediterranean, landed some men sick of the plague here, where barracks were erected for their reception. They served as the first nucleus for the village. Some semblance of truth is given to this view by the ruins of a chapel called "Ruota," which may be a corruption of Rodi (Rhodes). A little hamlet of the same name also still exists, and is the chief point of attraction for a favorite excursion in this neighborhood. And, finally, almost on the summit of Cape Nero, the quaint old tumble-down village of Colla di Rodi is built. "The visitor will find here what he would little expect to see in such a remote and obscure place, a library of six thousand volumes, and a collection of one hundred and twenty original paintings, most of them by the old masters, Fra Bartolomeo, Bassano, Caracci, Paul Veronese, Salvator Rosa, Domenichino, Guido Reni, Andrea del Sarto, Carlo Dolce, etc."[2]

Some years ago the physician to the then Empress of Russia was sent on a tour of investigation, having for its object the discovery of the most sheltered spot on the Riviera. After careful search and inquiry he selected Ospedaletti as the most favored site, and one generally credited with being two degrees warmer than any other resort on the whole coast. As soon as this became known, and under the speculative leadership of the Crèdit Foncier, of Paris, the land was quickly bought up, a huge and magnificent Casino was erected, and numerous improvements promised. This premature little boom effectually killed the place. It never became the fashionable station that it was fondly hoped could be created over night. To-day the Casino looks like a huge white mausoleum in all the loneliness of its forsaken grandeur. Apart from this structure, the clean and new Hotel de la Reine, a few minor pensions, several villas, and the rather dirty old village, constitute all there is to Ospedaletti. For undergoing a course of absolute quiet and repose in a sunny, well-protected situation, no more suitable place has yet come to my notice on the Riviera. American physicians

[1] L'Hiver dans les Alpes Maritimes, p. 110. Paris: 1891.

[2] Macmillan: The Riviera, p. 208. London: J. S. Virtue & Co., 1892.

could do worse than recommend it, where that line of treatment promises well for their patients.

Although most Riviera books only vaguely intimate it, there is no doubt that little Ospedaletti is more effectually protected from winds than almost any other resort on this coast. Moreover, it gets the sun early and keeps it late. There is also less blinding calcareous dust there than, for example, at Hyères, Cannes, or Nice.

Ospedaletti spreads out for something like a mile along the head of a small crescentic bay. The eastern headland of this bay is formed by Cape Nero, and the western extremity, much farther from the village than the former, by Cape Sant' Ampeglio. Thickly planted olive hills surround the place, relieved in the plain by orange and lemon trees, and the usual array of graceful palms. Successive girdles of mountains protect it from the icy northern blasts, but less in a northeasterly than in a northwesterly direction. It is fully exposed only to the warm westerly marine breezes.

Immediately behind the village there rises a hill of gentle slope, and a number of mountain torrents of mild proportions trace their undulating course seaward. The place is so hedged in as to constitute a veritable sun-trap, and to preclude the possibility of ever being transformed into a town of any size.

It is a pity that the railroad tracks are laid close to the sea, as the beach is a sandy one, and a pleasant promenade along the shore has thus been ruined. As at Bordighera, the evening chill is less sudden and less intense than at resorts backed by bare rocks.

The drinking-water used at Ospedaletti is soft, sparkling, and pure. It is taken from the same source as that which supplies San Remo, *i.e.*, Argallo. It could not be better, and is by long odds the best potable water to be found on the Riviera.

If the French speculators, instead of erecting a huge Casino, had utilized the hot sulphur springs found a few steps beyond the village, the permanent nucleus of an attractive sanitarium might easily have been established. As it is, this means of adding to the natural advantages of the place has been overlooked or neglected. Gouty and rheumatic elderly people should do very well at Ospedaletti, and a bathing establishment of modern type would soon be welcomed by discerning invalids of that class.

It is hoped that this brief sketch may help to make known the possible resources of a little place that has, as yet, been scarcely mentioned by medical writers on the Riviera.

(To be continued.)

THE TEST FOR THE COMMA BACILLUS.

To the Editor of the Medical Record.

In view of an impending epidemic of cholera in this city, and probably in the greater portion of the other cities this side of the Atlantic, I desire to give your readers the usual method of examination of dejecta of suspected patients as practised in the Bacteriological Institute at Berlin last summer.

The articles necessary for the examination are: 1. A microscope with Abbe's condenser and the oil immersion system. 2. A solution of fuchsin 1 gm. (Rubin) in 90 c.c. distilled water and 10 c.c. alcohol. 3. A few pipettes, glass rods, object-glasses or cover-glasses, and slides. 4. A few platinum wires melted or soldered to the end of glass rods. 5. A few hollow slides. 6. Ten to 12 glass plates or glass panes about 12 ctm. long and 9 ctm. wide. 7. About a dozen ordinary flat plates. 8. An alcohol lamp, or gas being preferable, a Bunsen burner. 9. A number of test-tubes with sterilized gelatine. 10. A number of test-tubes with sterilized nutrient bouillon. 11. A few Erleymer's glasses, about one-third filled with one per cent. pepton solution; 1 gm. pepton, 0.5 gm. chloride of sodium, 100 gms. distilled water. 12. Concentrated sulphuric acid.

The dejecta of suspected patients are scattered in as thin a film as possible on a plate, and this is carefully examined with the aid of a platinum wire for a mucous flake, "Schleimflocke," which is laid on the edge of the plate and isolated.

From this we take a piece the size of a pin's head, and sterilize a platinum loop (by drawing it through a Bunsen burner), and then rub it on a cover-glass until it is evenly divided; then remove all superfluous material by pressing another cover-glass over it, and allow it to get air-dry.

Then draw it three times through a Bunsen burner in the same manner as we proceed in the examination of sputa for tubercle bacilli, and by means of a pipette add a few drops of the fuchsin solution for about one to two minutes to the cover-glass, and then wash it off in distilled water. Then add a drop of water to the cover-glass, lay it on a slide, and examine it with the oil-immersion system.

If we wished to preserve the specimen we could, after staining with the fuchsin solution, wash off the excess of stain with distilled water and allow it to get thoroughly air-dry, then add some Canada balsam.

In some cases called "foudroyant," where the intestinal contents have a colorless or pale red color, with slimy (mucous) flakes or with a flour-soup mass, we will frequently find, especially, however, in the reaction period with cases running a slow course, no mucous flakes, but large quantities of blood. Here there are, besides cholera bacilli, large quantities of other micro-organisms, and sometimes only the cholera bacilli sparingly, so it is advisable, to render a diagnosis absolutely positive, to add to microscopical examination the examination by the aid of "cultures."

Cultures can best be made in "hollow slides" by smearing the border with vaseline, then bringing a small drop (from a platinum loop) of sterilized bouillon into this hollowed groove of the slide, and inoculating this latter bouillon with the smallest possible particle of the suspected mucous flake. The cover-glass is carefully laid on the vaseline, which serves to render the groove air-tight, and also prevents the evaporation of this drop of sterilized bouillon, which is then laid aside in a temperature of 20° to 22° Celsius. The room can be heated if the temperature of the air is below this. It takes about twenty hours to have the bouillon turbid, and this slide (hollowed, containing this infected bouillon) can be examined with the oil-immersion without disturbing the culture. The best place to examine is the border line, and even if but few cholera bacilli were formerly present, they grow so rapidly that they will be easily recognized by their curved shape.

Culture Method by Schottelius.—Take 100 to 200 c.c. of the suspected dejecta from intestinal contents and place them in a beaker glass containing 250 to 500 c.c. of mild alkaline meat bouillon, and mix thoroughly; then let this mass stand about twelve to twenty-four hours at a temperature of 30° to 40° Celsius. After this time the cholera bacilla have usually increased in numbers and are found on the upper layer of the fluid. By introducing at the upper layer a platinum loop, and taking out a small drop (about the size of a lenten seed), and rubbing it on a clean cover-glass, we allow it to dry thoroughly (air-dry); then draw it three times through a flame to fix it, and finally stain, as previously described, with the fuchsin solution.

Post-Mortem Tests.—To examine suspected intestinal contents I open the abdominal cavity carefully and ligate, with aid of two stout cords or twine, a piece of the ileum (about three to four centimetres in length), well filled with fecal contents, near the cæcum. It is well to apply a ligature close to the upper ligature, and another below the lower ligature, and cut between the two ligatures so that the intestinal contents will not be spilled in the abdominal cavity and prevent the completion of the autopsy. It is well to cut out a piece of the intestine, about three to four centimetres in length, from the upper portion of the ileum,

and to lay the excised portions into ordinary water until ready for use, *i e.*, examination of contents. The method is the same as has been described, *i.e.*, take a small piece of flocculent mucus, about the size of a pin's head and examine it. Gelatine stroke and stick cultures, and also potato cultures, can be made for examination. They also grow on blood-serum and agar.

A Practical Point is the following: Koch found cholera bacilli in the water of an East Indian tank. But it is the rule that the cholera bacillus does not develop very much in our ordinary water, owing to the presence of other bacteria which easily destroy the cholera bacillus; but they do develop marvellously in sterilized water (water free from bacteria); so, for instance, soup is an elegant medium for their development.

Human beings are usually infected through the mouth—*i.e.*, through food, etc.—and it is found that if the stomach is partly filled and has sour reaction (gastric juice) the latter acts as a barrier to the infectious material.

Cholera bacilli require for their growth a mild alkaline nutrient medium, and are very sensitive regarding mineral acids.

By adding 0.07 to 0.08 per cent. of muriatic or nitric acids to a neutral nutrient solution the growth of the bacilli was stopped. This statement is found in "Günther's Bakteriologie," page 210, and is made by Kitasota.

Louis Fischer, M.D.

40 Rivington Street, New York.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 3, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	46	15
Scarlet fever	36	4
Cerebro-spinal meningitis	0	5
Measles	59	8
Diphtheria	59	18
Small-pox	6	3
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

The Cigarette Epidemic.—Our national legislators still find time occasionally to attend to the public health. A report severely condemning cigarettes has been made to the Senate by the Committee on Epidemic Diseases. The committee does not believe that the Federal Government can do much about it, except, perhaps, to forbid their importation and prevent their manufacture in the District of Columbia.

A Useful Suggestion.—Professor Laborde declares that violently jerking the tongue will excite the respiratory reflex in cases of drowning, etc., when other means have failed, and a story is going the rounds of the press relating how two young men were saved by him at a time when their lives were despaired of. As the method is simple and within the reach of everyone, there can be no objection to giving it a trial.—*Medical Press.*

Mr. Huxley and the Title of "Doctor."—Mr. Huxley, it seems, though M.D. of Breslau and M.B. of the University of London, and the happy possessor of endless doctorates of all sorts, objects to the title of "Dr." Huxley. He can stand being called "Professor," but draws the line at "Dr.," which many men seem to value so highly. Mr. Freeman and Matthew Arnold, we are told, objected to be called "Professor." It is all intelligible enough. Great men have a consciousness of something *in* them that supersedes all the aid and adornment that titles can give. "When unadorned, adorned the most." And in this they are a warning, if not an example, to lesser men, who attach an excessive importance to the mere embellishments of a name, and very often to the assuming of a title which they do not possess.—*Calcutta Medical Reporter.*

Napoleon's Pulse.—According to Corvisart, the normal pulse rate of Napoleon Bonaparte was under forty beats in the minute.

An Efficient Oxytocic.—Among the Kirghiz tribes of Central Asia it is the custom, in cases of difficult labor, to seat the woman on a horse and make him gallop for a couple of miles over the steppe.

The English Disease.—The poor, unenlightened Mohammedans of Damascus, who couldn't be expected to know better, call drunken men victims of "the English disease."

A Fatal Curiosity.—A weaver in Accrington, England, put a turpentine stupe over his abdomen for the relief of a severe colic. It did not seem to burn as much as it ought, and he struck a match to see what was the reason. The match ignited the turpentine and the man was burned to death.

DISEASES AMONG INDIANS.

BY A. B. HOLDER, M.D,

MEMPHIS, TENN.

ASSISTANT PROFESSOR OF PHYSIOLOGY, MEMPHIS MEDICAL COLLEGE, ETC., FORMERLY AGENCY PHYSICIAN, CROW RESERVATION, MONTANA.

ERUPTIVE DISEASES.

FROM no eruptive ailments are Indians free, and some of them have at times raged with a violence unknown among other races, save perhaps among soldiers in time of war.

Small-pox has played sad havoc with some tribes. During the year 1873, one-ninth of the Santee Sioux, of Nebraska, died of small-pox. In 1832 that contagion swept away great numbers. In 1837 and 1838 small-pox destroyed the Mandans, a tribe occupying the shores of the Upper Missouri, entire families perishing.

In the summer of 1878, of the Mohave and Chimehuevis Indians of Arizona, numbering only eight hundred and thirty eight souls, one hundred and seventy died of small-pox. There are few tribes who do not bear in pitted faces and sightless eyes evidences of its ravages. They hold it in mortal dread, and a case or report of small-pox will cause greater consternation and stampede in a camp than a hostile invasion.

For the seven years ending in 1888, only eighty-one cases are reported from all agencies; while the mortality from the milder disease, measles, was eighty-three in the single year 1888. In connection with the decrease in cases of small-pox reported, it is well to observe that in these seven years were vaccinated 21,633 Indians, or nearly double the number born during that period.

The rapid spread of small-pox and the fearful havoc it has played in the Indian population in former years I believe were due, in great measure, to their unprotected condition. As vaccination becomes more general among them the mortality from small-pox will be immensely decreased.

In the last few years no epidemic of small-pox has raged among any Indian tribe.

At White Earth Reservation, in 1883, an epidemic caused many deaths. In the little village of Hannahville or Cedar Creek, near the Mackinac Agency, Mich., in 1882 there were twenty deaths out of a population of only two hundred. Fifteen deaths occurred among the Southern Utes in 1883. It raged in every village of the Pima tribe in Arizona in 1884.

In the seven years frequently referred to there were more than six hundred cases of *measles*. This disease, so trivial under favorable hygienic conditions among whites, finds in the Indian a most vulnerable pulmonary system, and meeting little resistance there, by disabling that leg of the vital tripod causes many deaths. In the year 1888, of one-hundred and eighty-seven cases eighty-three died. Of sixty cases in the boarding-school at Osage Agency, I. T., in 1882, there were five deaths, notwithstanding the children received careful nursing from the employés, showing that even under favorable hygienic conditions the resistance of Indian children to this disease is below the average.

Dr. Treon, of Crow Creek Agency, in a severe epidemic in 1888, lost one in fifteen cases treated in camp; but of one hundred and thirty cases treated in the boarding-school, where favorable surroundings and good nursing could be procured, not one was lost.[1] He observed that the stage of incubation was longer than among whites, and that there was greater tendency to severe capillary bronchitis; which latter fact receives ready credence from those familiar with the Indian constitution.

An epidemic prevailed among the Apaches of San Carlos Agency, Arizona, in 1881, and among the Pimas in 1883, causing many deaths.

Joseph's band of Nez Percés, in the spring of 1888, after their return to Washington Territory, suffered severely from a malignant form of measles. On certain Sioux Reservations in Dakota, it has been the occasion of such mortality in the last two years as to cause decrease in census of tribes who to that time were steadily increasing.

Epidemics of whooping-cough have usually followed measles, as in white communities, and have been more fatal in about the same degree as measles. Among the Sioux at Devil's Lake in 1879, at Lower Brulé in 1882, among the Round Valley Indians of California in 1886, and among the Mohave and Chimehuevis of Arizona in 1886, this disease prevailed and many deaths among children were caused by it.

Mumps[2] occurs frequently and pursues the same course as among whites. An epidemic is at present raging on the reservation where I write, but seriously interferes with comfort in few cases. Metastasis to the testicles has occurred frequently.

Erysipelas was treated in 2,065 Indians out of 500,000 cases of all diseases reported in seven years. Of six hundred and fifty in 1888, sixteen were fatal.

A small epidemic with some points of interest occurred in my practice on the Crow Reservation, during the winter of 1887 and 1888. There were fifteen cases, fourteen of which were in the boarding-school of forty-five pupils. The remaining case was a young white man living a few rods from the school, and who suffered a most severe attack after receiving a scalp wound from a falling bell clapper.

Two cases of the fourteen in the school were plainly traumatic. An Indian boy received a scalp wound from a boot thrown at his head, cutting a gash an inch long. This healed kindly. Eight days after, the boy complained of headache and pain about the wound; eyes suffused, diarrhœa, temperature A.M., 100¼° F., P.M., 101° F. The next evening temperature was 104° F., vomiting and diarrhœa, and at times violent delirium. The succeeding morning temperature was normal and pain and swelling gone from wound, and patient about well.

About the same time of above injury, another boy fell against a stove and received a scalp wound above the right temple, which healed readily. Two weeks later the seat of the wound became tender; around it, in a radius of two inches, the scalp was sensitive and elevated. About an inch from the wound toward the right ear was a small lump under the skin, tender, movable, giving to the fingers the sensation of a dermoid cyst. Another just like it, as large as an almond, just behind the right ear. Tendon of right side of neck sore. Temperature reached 102½° F., and gradually lowered, tenderness and "lumps" subsiding.

The remaining twelve cases were apparently without open lesions; all occupied the usual seat on face be-

[1] Cincinnati Lancet-Clinic, November, 1888, p. 586.
[2] While not an eruptive disease, this is noted here.

tween brow and lips. Three were typical severe cases with usual symptoms, and nine, four boys and five girls, were peculiar.

In the first case my attention was called to an enlarged gland in the neck. I observed two or three cervical glands enlarged and tender. The same evening I found a cellular swelling with well-defined margin including these glands, extending onto the face, under the eye, and to the bridge of the nose; very little redness or tenderness. The girl was abed, but had no appreciable fever and was entirely comfortable. The next day the swelling subsided, and she was quite well. Several other girls were similarly affected, some remaining abed a part of a day, some not at all; none had perceptible fever, no vesication, no desquamation. One boy had a single gland just in front of the ear, swollen and tender, and the eye on the same side a little suffused and watering; another had one eye much inflamed only on the outer side of the ball; both were well the second day. Another had slight flush over face, tongue pointed and red, bowels constipated and sensitive to pressure, temperature from normal to 100½° F. for four days, and well.

Another temperature, 9 A.M., 101¼° F., tongue pointed and red, light-coated, right eye injected, right submaxillary glands enlarged. Headache, temperature, 6 P.M., 102° F.; next morning, 100½° F., 6 P.M., 102° F. Cheeks suffused. Third day, A.M., 100½° F., P.M., 100¾° F. Fourth day, temperature normal, and returned to duty.

These cases are notable for their mildness and brevity. Several of them could not possibly have been diagnosed erysipelas, except in the light of the typical cases occurring in the same building at the same time.

It is interesting to observe, occurring in the same epidemic, from the same source of contagion apparently, under the same constitutional and hygienic condition, cases so mild as the suffusion for a few hours of a single eye or swelling of a single gland, and others so severe as to cause fierce delirium or (in the case of the young white man) profound coma for some hours with extensive vesication, desquamation, and loss of hair.

There was no outside source of contagion in this epidemic. There had, however, occurred in the same building, the preceding year, a dozen or more cases of the mild form described above, and the bacilli of Fehleisen doubtless maintained winter quarters in the building. Several of the same patients had suffered the year before.

Such mild cases often puzzle the surgeon. Drs. Grindon and Fry, in a discussion before the St. Louis Medico-Chirurgical Society, recognize this difficulty and report as an "erythematous affection"[1] cases quite similar to the above.

Subsequent to this epidemic a case was seen in an Indian policeman, peculiar in this, that the lesion in which the inflammation began being on the finger, the most serious inconvenience from the attack was from a phlegmonous swelling becoming a sluggish abscess, which suppurated many weeks, situated in the sheath of the biceps near its insertion.

Constipation.

The Indians are universally and persistently constipated. I incline to the opinion, however, that this is an ailment common to the human family. Among 505,940 Indians applying to Agency Physicians for the seven years between 1882 and 1888, inclusive, were 36,254 who sought relief from constipation. These figures may be somewhat exaggerated, as I shall explain later on, but, this admitted, constipation is more frequent than we should expect.

An explanation given me by a negro who has lived many years among the Crow Indians, I think, possesses a certain amount of truth. He attributes it to the fact that formerly they lived exclusively upon meat, whereas now they have an insufficient supply of meat and much of their food is bread, made of bolted flour, and potatoes, both cooked without grease. To this may be added the fact that the wild berries, which are eaten both from the bush and dried for winter use, abound largely in tannin and tend to constipation.

School children, on the contrary, to whom is furnished a much greater variety of food, suffer much more frequently from laxness of the bowels than from constipation.

As I have said, it is likely the extent to which constipation exists is over-estimated, from the fact that Indians, like other races, find, or think they find, in free purgation a cure for all ills.

An Indian to whom I had given an anti-syphilitic solution, returned the next day, and after indicating by suggestive signs that it had neither purged nor caused emesis, made the sign of inquiry meaning, "As it neither purged me nor vomited me, how can it do me good?"

When an Indian seeks a purgative medicine, I often find on inquiry that he has had regular daily evacuations, and that it is not for constipation but for some other ailment that he prescribes the cathartic.

The ancients made the spleen the seat of melancholy and other ills. Those people living in the malarial belt of the great Mississippi Valley, with whom most of my life has been passed, charge to the liver all the ills from which flesh or mind may suffer, while the Indian declares *me spör' kow-ekē*, "my stomach is bad," and is truly nearer the right.

This mania for purging, which I believe exists among all races, is worthy the consideration of the physician, first, because an idea cannot be of such widespread acceptance and not contain much truth, that a thorough evacuation of the alimentary canal must indeed be beneficial in many different ailments; and second, that he may intelligently combat the enormous *misuse* of purgatives.

It is suggestive that the popular restriction of the word "physic" to a cathartic medicine is paralleled by the use among the Absaraka Indians, the only tribe with whose language I am familiar, of the word *e'y-she'-o*, which etymologically means any medicine to be taken internally, but which, alone, when used, is constantly restricted to a cathartic medicine.

In connection with constipation among Indians it is interesting to read the following opinion, expressed by a St. Louis physician before a medical[1] society of that city. "The constipation so common among civilized people, and especially females, is in some measure due to the restraint of clothing and modesty; if children and men and women were no more restrained by clothing and a sense of what is decent and proper than the beasts of the field, constipation in the human family would be as rare, no matter what their ordinary diet, as it is among the beasts of the field." Now, the Indian will leave the tepee just as the dog will go out of the house or kennel, but he (or she) will stop within ten feet thereof, and in sight of the entire village, when and where the inclination overtakes him, spread the all-useful blanket above his head and obey with commendable promptness the calls of nature—still he is constipated.

Conjunctivitis.

Cataract is not infrequent, but other forms of eye disease not conjunctivitis or sequelæ to it are in proportion so rare as to be ignored here. Of five hundred thousand cases of all diseases treated among Indians, nearly sixty thousand were conjunctivitis, a much larger number than of any other single ailment. Trachoma, pterigium (and more rarely iritis) are frequently seen as sequelæ or result of the same cause.

The causes of the great prevalence of conjunctivitis may be briefly enumerated—smoke, dust, snow, paint, dirt. It is the habit, as widespread as the Indian race, to paint the face constantly, and the body on occasion. This paint is applied in part only for cosmetic effect, it is used as well for the same reason that Orientals anoint with oil, and other civilized races wash with water. The Indian says it protects the face from the sun in summer

[1] Courier Medical, December, 1887.

Courier of Medicine, February, 1888.

and from cold in winter. It is applied to the new-born baby, and is part of the preparation of the body for the grave. The paint used is usually an earth pigment, as sienna or umber, but frequently contains the more harmful mineral colors. It is applied freely about the lids and lashes, and cannot but have an injurious effect. Accumulation of the variety of material we call "dirt" is the necessary result of the substitution of the application of paint for ablution with water. The alkali found throughout the arid cactus belt of the West, the home of many of the Indian tribes, is painfully irritating; particularly as in the same region usually prevail frequent high winds lifting the dust and sand, and driving fine, irritating particles into the eyes of the unfortunate inhabitants.

One who has ridden all day with the rays of a bright winter sun glittering on endless fields of snow, can appreciate the pain of "snow blindness;" yet the Indians have strong eyes, going constantly in bright sunlight without hat or other protection for the eyes; but those of the Northwest, who must endure the glare of the sun on the snow for four or five months, suffer much from conjunctivitis from this cause.

Perhaps the most potent cause affecting the large part of the race who continue to live in the primitive method, is smoke. Their house, the tepee, is a conical tent with an opening at the apex for the exit of the smoke; but smoke is proverbially perverse, and frequently will not exit at this opening. The Indians crouch in this for hours until the wind or other factor changes and the smoke ascends. The result is severe irritation of the delicate membrane and resulting conjunctivitis, rendered chronic by persistence of the cause.

Epidemic conjunctivitis, the form usually called catarrhal, I have not seen. It may however exist, as March, the month in which we would expect it, is called in the Sioux tongue the "sore-eyed month," indicating great prevalence of the disease at that season.

Notwithstanding its great prevalence, conjunctivitis is not often serious in its results, and blindness is not a frequent infirmity among Indians.

(To be continued.)

AN EFFICIENT METHOD OF CONTROLLING HEMORRHAGE AFTER SUPRA-PUBIC PROSTATECTOMY.[1]

By E. L. KEYES, M.D.,
NEW YORK.

No operation upon the genito-urinary tract is, in my opinion, less technically elegant than a thoroughly performed supra-pubic prostatectomy.

I do not, of course, refer to the first step of the operation—the supra-pubic cystotomy, or even to such minor forms of prostatectomy as may be included in the cutting or snaring away of outstanding pedunculated lobes, or even the prostatic bar, the nipping out of which may be æsthetically performed, carried out under the supervision of the eye, and, indeed, be a rather graceful operation; but what I do mean is the thorough evisceration of the prostatic body, the cutting, snipping, gouging, twisting, tearing operation and forcible technical manœuvres required to shell out and do away with such portions of the prostate from its fibrous investing capsule as it may seem proper, in the mind of the operating surgeon, to remove.

This major operation cannot be done under the guidance of the eye. The bladder, of course, is opened, the eye inspects the offending redundant tissue, and the mind takes in the situation and decides upon what must be done; but after this, when the first incision has been made into the prostate, the intelligent finger must direct the work at the bottom of a well of blood, and no matter how vigorous the operator or how brilliant his execution, a large amount of the vital fluid must of necessity be lost during the operative manœuvre alone.

[1] Read before the New York Academy of Medicine, April 7, 1892

Of course, the capacity for bleeding varies in different subjects. Some of the fibrous prostates bleed hardly at all, while others, of the soft, succulent, juicy variety, shed out the precious fluid upon each fresh incision to an extent that is alarming—even revolting—to the surgeon not familiar with this kind of surgery.

It gives the whole procedure an aspect of brutality, shared by no other operation upon the genito-urinary tract with which I am familiar, unless it be a lumbar, extra-peritoneal nephrectomy, in a fat subject, performed by an inexperienced operator through too small an external incision. This rivals—perhaps excels—prostatectomy in the gross appearance of apparent brutality.

This rough operation has to be done very frequently upon subjects particularly unsuited for enduring the strain of severe hemorrhage. The prostate, in our present stage of medical knowledge, does not usually justify operation in the earlier periods of its overgrowth. At this time the moderate functional disturbances to which it gives rise are tolerated by the patient, and elected to be endured rather than the alternative of a grave operation, the mortality of which, even in the best hands, is so exceptionally high.

Therefore the sufferer compromises with his misfortunes, and slowly drifts along into a constantly progressive deteriorated condition; his ureters enlarge, his kidneys, acting under back pressure, perform their function imperfectly; that general fibrosis of the entire genito-urinary apparatus, which has been crystallized into a pathological entity by Guyon under the name of prostatism, goes on; the finer arterioles become sclerotic, and bundles of fibrous tissue replace the natural muscular structure and squeeze out the vitality of the tissues making up the entire system. To this is added that natural fatty atrophy which attaches to all the tissues in advanced life, where nutrition is defective and deteriorating changes are taking place.

Polyuria, defective elimination of the waste products of the economy, and albuminuria, in many instances, mark the patient's retrogressive steps. Failure of nutrition is shown by his anæmia, which is often very pronounced, his impaired digestion, and the general depression and imperfect performance of all of his functions.

Finally, when life becomes a burden, and when he grasps at any straw that offers to furnish him relief, at no matter what risk, then the surgeon is called in and prostatectomy proposed and accepted.

I am in the habit of looking upon a patient in this condition very much as I would regard an individual in an open field bordered by a deep and rapid river. The individual cannot swim, but an enraged bull is chasing him, and he must either suffer himself to be impaled or gored to death (this is his prostatetic progressive disease), or he must cast himself into the flood and trust to some kindly Providence to fish him out (this is prostatectomy).

How many patients die after prostatectomy from hemorrhage I do not know. Probably none die directly from loss of blood. No large arteries are severed and the bleeding does spontaneously arrest itself after a time. Moreover, the means already in use by the profession generally suffice to moderate the hemorrhagic loss. Yet we all know that a certain positive proportion of these cases suffer severely after their operations, and many, when they die, die within a few days without suppression of urine, their demise being ascribed to shock, exhaustion, failure to rally, and the like; and what proportionate influence the factor of hemorrhage may have exercised in this disastrous eventuality is and must remain a matter of conjecture.

It certainly cannot be denied but that a satisfactory means of controlling hemorrhage from the eviscerated prostate, after the rapid performance of the operation, must be an element which will eventually help to lend to it statistical advantage.

The common means of arresting hemorrhage after operations upon the bladder which has been opened

above the pubis, need only to be mentioned to be familiarly recalled by all of you. They are briefly the ligature in accessible positions, pressure for moderate oozing, the catgut stitch passed with a short curved needle through the tissues about the point of incision, or across the narrow hemorrhagic area; the Paquelin or other cautery; the electric cautery as applied through a platinum wire loop; forci-pressure forceps applied and left *à demeure*—a manœuvre I have on more than one occasion successfully adopted.

I show you here two especially curved long forci-pressure forceps designed for use within the bladder. With them small morbid masses, particularly if pedunculated, may be grasped and removed under the eye without hemorrhage, the catgut suture being applied with a needle through the underlying tissues before the forceps is removed, and tied before the hemorrhage has had a chance to more than fairly express itself.

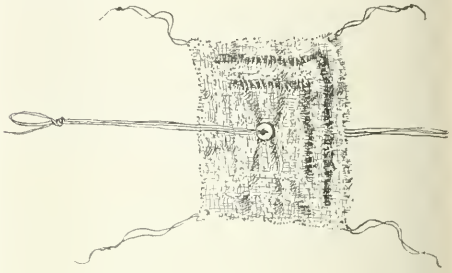
The Albarran tubes, which I here show you, constitute another means of controlling hemorrhage. They have been used successfully upon animals and upon the human subject, by being passed into the urethral orifice on either side and left there to drain the urine away, while the outer parts of the bladder are packed with any suitable substance for the purpose of exercising pressure. The whole bladder may be packed (without the use of these tubes) with gauze or sponges tied upon a string, and subjected to uniform pressure for a number of hours, without harming the kidney; but the pressure is distressing and the time during which it may be employed limited. The excavated prostate itself may be crowded full of iodoform or other gauze, but it does not stay well in place, and excessively hot water may be injected freely and for a long time into the bladder with advantage for the purpose of controlling hemorrhagic oozing; but during its use a considerable amount of blood is necessarily wasted.

I was so forcibly struck with the unnecessary loss of blood in some of these operations that I performed last year that I gave considerable thought to a suitable method for arresting the hemorrhage in this funnel-shaped cavity left by the excavation of the prostate, and finally hit upon the device which I have to offer you to-night.

It need not, of course, be employed in every case, but in all those in which the patient is particularly feeble and anæmic, and in which the personal hemorrhagic tendency is high, it can certainly do no harm, and, it seems to me, must always do good. I have only recently gotten the size and shape of the plug which is to arrest the hemorrhage into what I believe to be about the proper form. I show you here two prostates—the last two that I have removed. The removed fragments in one weighed two ounces and a half, and in the other a little over two ounces. The amount of anæmia and general deterioration in both these old gentlemen was excessive. The plug was used upon both of them, and neither one lost, I may say, any blood after the dressing was placed. It was removed in one instance after twenty-four hours, in the other after thirty-six hours. In neither instance was there any considerable complaint of its pressure—nothing, at least, that a moderate amount of morphine could not control, although it certainly was felt, and in neither instance was there any recurrent hemorrhage.

The plug, which I show you here, is something like what is customarily used after perineal cystotomy, in the form of a shirted cannula, excepting that in this instance there is no need of a cannula, because the supra-pubic wound in the bladder must be left open for the subsequent removal of the plug. The urine flows away unobstructedly.

The tampon is made of bichloride gauze. A square of four thicknesses of gauze is first cut, the length of each side being about six inches. Upon this are placed eight thicknesses of gauze cut square, each side measuring four inches, and upon this eight other thicknesses of gauze, also square, the side measuring three inches. Centrally, upon the three-inch pad a small white shirt-button is tied by stout silk ligatures, transfixing the pad and tied upon the six-inch square surface. This central button also has a piece of silk attached to it, running out freely in the direction away from the three-inch surface. This is to facilitate extraction. Each of the corners of the six-inch pad is stoutly tied with a piece of silk, and the silk from each of these four corners is knotted at its end into a double knot, while the silk running out backward from the button is tied with a single knot, for the purpose of distinguishing which is which when making the extraction; although practically it will be found that they must



all be made taut and pulled upon all together in order to effect removal with the greatest care and facility.

In the first of my cases I passed a soft bulbous olivary French catheter through the urethra into the bladder and out through the supra-pubic wound, and tied my double silk upon the end of it, and with the silk making traction along the line of the urethra, drew the tampon powerfully down into the funnel-shaped excavation of the prostate, and tied the double ligature over a piece of soft gauze at the urinary meatus upon the relaxed penis.

In the second instance (because the patient also had deep urethral stricture) I made a perineal urethrotomy, and by direct traction through the perineal incision upon my tampon, drew it firmly into place, and tied the strings over a gauze perineal pad.

In both instances the subsequent removal of the pad was comparatively easy, and its effect in carrying out the function for which it was designed manifest and satisfactory.

I have thought of other pads, such as pear-shaped rubber balloons, which might be inflated, and which would be softer, and the removal of which, after collapse, could be more easily effected; but my experience with similar contrivances for use in perineal cystotomy and in the rectum has been so unsatisfactory, on account of the lack of durable quality in rubber goods, that I concluded to rely upon this more modest design, and its satisfactory performance has left me no desire for a better substitute.

Since the reading of this paper I have received the following letter, containing a very practical suggestion, from Dr. Cabot, of Boston.

"3 Marlborough Street, Boston, July 6, 1892.

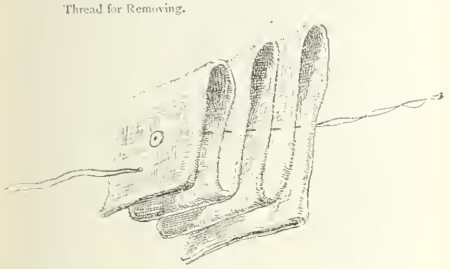
"Dr. E. L. Keyes, New York City.

"Dear Doctor Keyes: I have, since my return from Richfield Springs, had occasion to use the graduated tampon for stopping hemorrhage at the neck of the bladder, that you spoke of there. It was a case where I removed a tumor as large as a small orange, which grew from the bladder-face of the left lobe of the prostate, and from the bladder wall in its immediate neighborhood. The bleeding was very profuse, and was not stopped by injections of hot water. I carried the tampon down, bringing the thread that passed through it out through a wound which I had previously made in the perineum. It answered admirably in stopping all hemorrhage, but I was not quite sure that I did not make it somewhat large, and that it may not have hindered the escape of urine from the ureters somewhat during the first few hours. It

is difficult to say about this, as the urine might naturally be scanty in any event.

"I make a drawing at the bottom of this, of an arrangement which I think might work, and by which I think the tampon might be somewhat easier of removal. It consists in a long strip of gauze, the edges of which could be rolled in and stitched so that there should be no loose, frayed edges, and which could then be doubled in

Thread for Removing.



Thread for Holding in Place.

the way I indicate and run on to the silk to which is attached the button. It could then have another thread attached to the upper end to remove it by. This could be drawn into the neck of the bladder as firmly, I think, as any compress; but on loosening the thread which passes through the perineum and then drawing on the upper thread, it would come out in a long strip, much as the packing which one applies to a bleeding uterus does.

"It seems to me that this has some advantage in the ease with which it could be removed. The compress that I used may have been somewhat thicker than was necessary, but it came out, as they told me, pretty hard. I was not present at its removal, the patient being under the care of other physicians out of town.

"Thanking you very much for this idea, which worked well in my case, I am

"Very truly yours,

"A. T. Cabot."

ROTARY LATERAL DEFORMITY OF THE SPINE IN POTT'S DISEASE.

By JOHN RIDLON, A.M., M.D.,

LECTURER ON ORTHOPEDIC SURGERY AT THE CHICAGO MEDICAL COLLEGE; LATE ASSISTANT SURGEON AT THE VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, ETC.

It does not appear that true scoliosis is ever mistaken for spondylitis by surgeons at all familiar with deformities, but the converse of this proposition does not always obtain: Spondylitis readily may, and no doubt often is, mistaken for scoliosis until the progress of the disease or the results of treatment make manifest the error in diagnosis.

Lovett[1] referred to the early and constant occurrence of lateral deviation of the spine in Pott's disease, but did not admit the claim of Bartow,[2] that a true rotary element accompanied the lateral deformity.

Pott's disease, broadly speaking, is a tubercular osteitis or osteo-arthritis of some portion of the spinal column; true rotary lateral curvature, on the other hand, is lacking in all the characteristics of an inflammatory process, and appears as a chronic progressive deformity. Upon this basis the lines of differential diagnosis have been drawn. Objectively, scoliosis presents only its peculiar deformity; subjectively, there are no symptoms until the deformity has reached so great a degree that distant pain is felt from the pinching of the spinal nerves at their foramina of exit on the concave side. In my experience, pain is rarely found in cases where the diagnosis of scoliosis is absolutely certain, though the deformity be very great. Spondylitis, on the other hand, presents all the symptoms, subjective and objective, that go to characterize a tubercular process within, or in the tissues immediately adjacent to, a joint cavity, namely, restriction of normal motion by involuntary muscular spasm, weakness, or disability, and deformity primarily in the direction of comfort, and secondarily in the direction of bone destruction; distant pain is usually present, abscess is met with in very many cases, and paraplegia at times. In Pott's disease the general health is usually, often seriously, affected; in lateral curvature it is unimpaired. In the former the deformity usually looks posteriorly and is angular, while in the latter it looks to one side, is rounded, and is accompanied with a posterior bulging of the ribs on the side of the convexity, and a flattening on the other side. These differences are so great, it would seem that the diagnosis ought to be, as it usually is, very readily made. But cases of Pott's disease occur in which paraplegia and abscess do not appear, and pain is never felt; the kyphosis in very many is rounded, and may involve half or two-thirds of the dorsal and lumbar spine in a sweeping curve; early in the disease, often before the development of a posterior kyphosis, a lateral deviation is found, and this, as in Case I., may progress to a marked deformity before any posterior angle appears, or, as in Case II., the well-marked character of the rotation may obscure the true kyphosis.

Case I. (Figs. 1 and 2).—E. S——, male, eight years of age, first examined March 31, 1891. Good heredity.

Fig. 1, Case I.—Shows lateral deviation and rotation of the spine.

Before commencing to walk had measles and scarlatina; some time later had a fall which was followed by a lame back for a short time. Three years ago had pneumonia, which was not followed by any chronic cough; has always been very erect in his walk. About four weeks ago the mother noticed the spine curving to the right, and since then the deformity has rapidly increased. There is a right dorsal curve extending from the third dorsal to the second or third lumbar vertebra, with rotation; there are slight compensatory curves above and below; the "key note" position reduces the curvature somewhat, but does not wipe it out.

On the diagnosis of scoliosis daily exercises were given, and no corset or brace was applied. The deformity steadily increased, and at the end of six weeks a spring brace was applied; this was worn at night, and the exercises were continued. The deformity continued to increase

[1] Boston Medical and Surgical Journal, October 9, 1890.
[2] Annals of Surgery, July, 1889.

and the spine became more and more rigid, but there was no pain or other subjective symptom. On July 25th the photographs (Figs. 1 and 2) were made, and two days later, the exercises having been discontinued, he was partially suspended and a permanent plaster jacket applied. From this time on the jackets were renewed every six weeks; at each renewal the spine was found more flexible, and the curvature and rotation could be somewhat reduced. When last seen, in May, 1892, very little of either the lateral or rotary deformity remained.

This case was examined by two surgeons experienced in orthopedic work before treatment was commenced; they believed it to be scoliosis, as I did, and only from the results of treatment was the true diagnosis made.

Case II. (Figs. 3 and 4).—E. M——, female, fourteen years of age; first examined September 10, 1891. The deformity of the spine has been noticed for about a year; it has gradually increased, but there has been no pain or noticeable disability. There is a well marked left lateral curvature extending from the mid dorsal to the lower lumbar region, with well-marked rotation (see Fig. 3); this curvature is rigid, and there is a posterior, somewhat

Fig. 2, Case I.—Front view of same.

angular, curvature in its lower portion. There is a flexible compensatory curvature to the right in the upper dorsal region. Movements of the spine in various directions at the point of rigidity are painless.

The diagnosis of spondylitis was made from the rigidity and involuntary muscular spasm on attempted motion in the upper lumbar region; this was in opposition to the views of two general and one orthopedic surgeon who had the opportunity of examining the case. The treatment was by prone recumbency and an antero posterior, inelastic, leverage spinal brace. At the end of two months the lateral deformity and rotation had disappeared and the posterior deformity had been reduced one half. She was then allowed to go about wearing the brace. There had been a slight return of the rotation when last seen, in April, 1892.

From a consideration of the above, it appears to me that the results of treatment verify the diagnosis of spondylitis. The rotation of a true scoliosis would not have been so rapidly corrected, even if it could have been corrected at all. It appears further that the differential diagnosis must depend upon the presence or absence of muscular spasm, rather than upon the presence or absence of pain, or upon the character of the deformity; and in any case where the deformity is in the upper two-thirds of the dorsal spine and the presence of muscular spasm is doubtful, the degree of rigidity of the

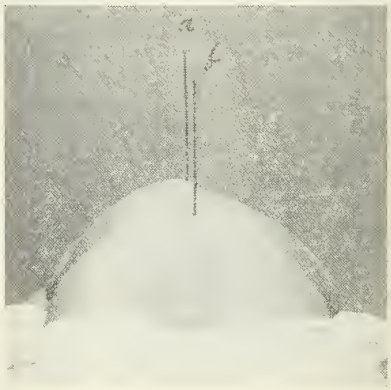


Fig. 3, Case II.—Rear view. Patient stands bending forward to the fullest extent, with finger-tips in apposition and pointing toward the toes. Line *a*, drawn from the tip of the spinous process in the middle of the curvature, and line *b*, drawn from a like point below the deformity, show the extent of the lateral deviation. The extent of the rotation is evident from a comparison of the outline of the back on either side of the line *a*.

curvature, as compared with the duration of the deformity, must receive careful consideration. The deformity of spondylitis rapidly becomes rigid; that of scoliosis only after it has been present for a long time.

Fig. 4. Case II.—Same patient standing. The illustration does not show distinctly the lateral deviation and rotation; on the other hand, it exaggerates the kyphosis.

In cases where any doubt still exists, the carefully observed results of treatment will ultimately decide the matter. Scoliosis, under treatment by forcible redressement and appropriate exercises, will not grow worse, but will usually slowly improve; spondylitis, under the same treat-

ment, will surely, often rapidly, grow worse. Treated by immobilization, the rigidity of the deformity of spondylitis will diminish, and at times the deformity itself grow less; under the same treatment, the deformity of scoliosis becomes more rigid, and the deformity itself is never lessened.

AN EXPERIMENTAL CONTRIBUTION LOOKING TO AN IMPROVED TECHNIQUE IN ENTERORRHAPHY, WHEREBY THE NUMBER OF KNOTS IS REDUCED TO TWO, OR EVEN ONE.[1]

This Suture is Applicable in Pylorectomy, Gastro-enterostomy, Anastomosis, Circular and Oblique Enterorrhaphy.

By M. E. CONNELL, M.D.,

Superintendent Milwaukee County Hospital.

Gentlemen, and Fellows of the Brainard: "As the twig is bent, so will the tree incline." Early in my student days, under the guidance of our revered brother member, and I believe the father of this society, Professor N. Senn, now of Chicago, I was led along the paths of experimental work. And in my later years of practice, as you are all aware, he has conducted at our institution many experiments on animals, some of which have attained a world-wide reputation.

Experimental work on the intestines has been a very interesting subject for some time past; some very ingenious ideas and some very complicated methods of enterorrhaphy have been devised, described, and tried; the aim in all cases being, first, to decrease the danger, and, second, to reduce the time.

My thoughts were directed to the suture which I am about to describe through the numerous objections that were raised against the use of plates, in intestinal anastomosis; the principal objections being, in my mind, the difficulty or impossibility of preparing or obtaining them in an emergency, the possibility of gangrene, the narrowing of the anastomotic orifice, and the blind end, or pouch, which is favorable to the formation of an enterolete.

My first step in this direction was a faltering one, though successful, Professor Senn afterward exhibiting the specimen to the students of Rush Medical College. This step consisted in using rubber rings about one or one and one half inch long, with one end cut diagonally, into the lumen of which was served with catgut a narrow tape, and to this tape was attached six sutures of silk. These pieces of rubber tubing were then inserted into the

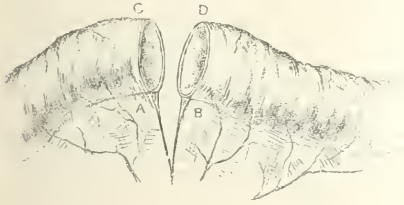

Fig. 1.

lumen of both cut ends of the bowel, the margins of which were inverted over the rubber tubing, and secured to the free end of the tape within the lumen of the rubber tubing, by a continuous suture of fine catgut; then each thread was picked up, divided and tied into position, bringing the serous surfaces in contact.

My aim was a modification of the plate operation, which had been so successful in the saving of time. I thought that with this method we would have a diagonal or oblique enterorrhaphy, with four or six knots, which would be fully as reliable as the Czerny-Lambert, and which could be accomplished in less time

In these experiments when placing the ends of divided intestines in apposition the bowel was given a half twist, so as to bring the mesentery of one cut end in apposition with the convex surface of the opposing end.

After several repetitions of this method, with some modifications each time, I finally rejected it, as too much time was consumed in placing the inverting suture, so as to bring the serous surfaces in complete apposition. My thoughts then turned in another direction, and I concluded to abandon all foreign material, and the result is a suture which seems so perfect in every respect that I deemed it worthy of mention, and this is my excuse for trespassing on your time and attention.

With this suture I have made twelve experiments, always on a dog; ten times it has been successful, and two dogs died. Chinese twisted silk, braided silk, and catgut have been used at different times.

The two deaths above mentioned were owing to a modification of the method, rather than to the suture itself being faulty; and I now have no hesitancy in saying that every dog can be saved. Two knots were used each time but once, and then I thought that it took a longer time to suture with one knot than with two.

As in the plate operation, this suture is very hard to describe in such a way that the hearer or reader may get all the points; but again, like the plate union, it is very simple and easy of execution, when the idea is once grasped.

After the abdomen is opened and the intestine exposed, a resection is made of any length desired, or only

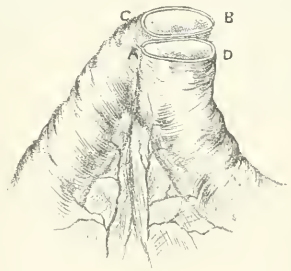

Fig. 2.

a V-shaped portion may be removed. If a resection is made, the bowel is cut diagonally or on the bias from above downward, that is, from the convex surface of bowel to the mesenteric side. When only a V-shaped portion is removed, the base of the V is at the convex, and the apex at the mesenteric side of the bowel, and the mesentery is slit down about one or two inches, as shown in Fig. 1, to allow the proximal and distal portions of the divided intestine to pass by each other, so as to bring the mesenteric side of one cut end in apposition with the convex surface of the other, as shown in Fig. 2 (*A* to *C* and *B* to *D*).

The intestines are held in this position by a thread passed through both ends, by a tenaculum, or by the fingers of an assistant, and the opposing walls are united with two sutures, by one of two methods.

In the first method, the first (or looped) suture is made by inserting the needle, armed with a suture, through the wall of the bowel nearest the operator, about one-fourth of an inch from the margin, at its convex end (*D* or *C*) from without inward, then passing it from the operator, at a distance of about three-sixteenths of an inch, through all coats of both walls which are in apposition, then back again through both walls, not drawing the stitch tight, but leaving it as a loop about one-half inch long, then

[1] Read before the Brainard Medical Society, July 8, 1892, at Oshkosh, Wis.

back again, leaving the stitch a loop as before. This is repeated until the whole of the opposing walls have been embraced in the suture, when with the last stitch the needle is brought from within outward, at about one-fourth of an inch below the margin, through the mesen-

Fig. 3.

teric end of the side on which the suture began (at *A* or *B*). The stitches should be taken about one-fourth of an inch from the margin of the cut bowel, and be about three-sixteenths of an inch in length; the loops may be left about one inch long or a little less, and on both sides of the suture as described above. At this stage the suturing will appear as shown in Fig. 3. These sutured

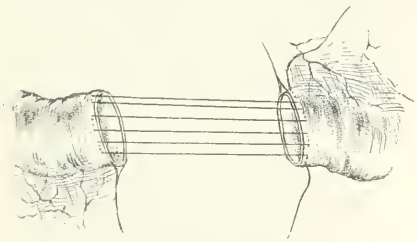

Fig. 4.

walls are next separated as far as the looped stitches will permit, when their relation will be as illustrated by Fig. 4. The two portions or ends of intestine are now turned over, bringing the two ununited walls in apposition.

Laying the loops to one side out of the way, the operator then joins these two walls together, with a suture the

Fig. 5.

same as the first, only that there are no loops, each stitch being drawn sufficiently tight to bring the serous coats into close contact. At this point the work will appear as in Fig. 5.

As the opposing ends of this second suture are drawn taut and held by an assistant, the loops of the first suture are seen to be above. The operator then takes up the ends of the first suture, and, as he draws them gently and steadily, he will be delighted to see the margins of the wound roll into position in a manner that will surprise him. "It slides into place as if by magic," said a bystander, on witnessing the experiment for the first time. The result of the work at this stage will look as in Fig. 6.

The sutures are next tied together at each end, care being taken to see that the mesenteric end is completely inverted; and, if catgut has been used, the knot should be reinforced with another of fine silk over the catgut. The

Fig. 6.

threads should not be cut off after making the first knot, as they are necessary for traction when making the second; after this the loose threads at both ends are cut off close, and the suture is complete.

This same result may be reached without the puzzling "turn" or "roll over" of the intestine, and with but very little difference in time, if the suturing is done as in the following method.

Fig. 7.

The preliminary steps are the same as in the first method, the cut ends of bowel are placed in position as illustrated in Fig. 2, and the first or tight suture is inserted as shown by Fig. 3, with the exception that, instead of leaving loops, all stitches are drawn tight. The work will then look as in Fig. 7.

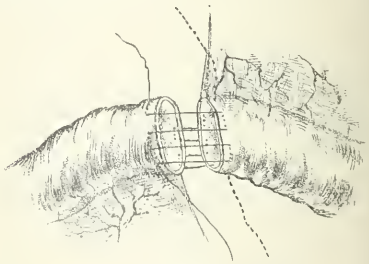

Fig. 8.

In making the second or loose suture the needle is inserted as before, from without inward through the wall of bowel, at the convex end, and passed out again on the same side; it is then crossed over the cut edges to the opposite wall, and a stitch is taken through all the coats about three-sixteenths of an inch in length, parallel with the margin of the cut edges; it is now passed back again, and a stitch is taken as before. This is repeated until enough stitches have been taken, when the needle is

brought from within outward through the mesenteric end, as described in the first method.

When this suture has been inserted, and before it has been drawn tight, it appears as in Fig. 8. The suture can now be drawn taut, when the magical inversion of the everted edges will take place, and the result is the same as that in Fig. 6. The knots should be tied as before described, and I feel that you will be delighted with the final result.

This method of suturing seems to be especially adapted to the removal of malignant growths at the pylorus. What is particularly striking is the fact that no steps to narrow the pyloric end of the stomach are necessary, which is obviously a great saving of time, not to speak of the attending risk.

The pyloric end of the stomach can be cut off obliquely, from above downward and outward, after it has been properly clamped, the length of the opening thus made carefully measured, and the pyloric end of the duodenum cut diagonally to the same extent, and the cut ends may then be sutured by either of the already described methods of enterorrhaphy.

The advantages which may be claimed for this suture are: That there is no foreign material inserted, as in the plate operation; no blind end in the oblique enterorrhaphy to act as a receptacle for waste material which might form an enterolete; the rapidity of the operation, as compared when using the Czerny-Lambert or other sutures; the freedom from danger of obstruction, by narrowing of the lumen, as the opening is diagonal in oblique enterorrhaphy, and in anastomosis it can be of any size, thus giving plenty of freedom for the passage of intestinal contents; and finally, the material for this suture the surgeon has always at hand.

Clinical Department.

THE TREATMENT OF CHOLERA.

By EDMUND CHARLES WENDT, M.D.,

NEW YORK.

[In view of the possibility of a cholera visitation we give the following account of the treatment of the disease quoted from Dr. Wendt's standard work on Asiatic cholera.[1]]

The Treatment of Premonitory Diarrhœa and Cholerine.—Under this and the following heading we propose to sketch such a general plan of treatment as we conceive to be in accordance with our present knowledge of the disease, but which is above all things supported by rational clinical empiricism. This may be profitably supplemented by some account of particular methods or remedies that have received the sanction of authority, or whose claims to recognition have been warmly urged, more particularly during the recent European outbreak.

In the prevalence of an epidemic, the safest rule in practice is to treat every case of diarrhœa, no matter how slight, with the utmost care, and on the principle that it may be premonitory of a grave attack of Asiatic cholera. It goes without saying that the physician must studiously avoid causing unnecessary apprehension, or spreading alarm among his clientèle. Yet by exercising the necessary amount of tact, the families composing his practice may be informed of the urgent necessity of attending immediately to the most insignificant intestinal derangements, that ordinarily might be disregarded.

If slight diarrhœa occurs and is clearly traceable to errors or excess in eating, and if there is reason to believe that undigested food is still irritating the bowels, a mild laxative, such as castor-oil or the usual salts with a little opium, may be safely given. No possible harm can result from a single dose of an unirritating laxative. And even should the sequel show that the case was one of choleraic diarrhœa, the physician may rest assured that the attack was not aggravated by his remedy. No sooner has the laxative produced its effect of removing the offending matters, than any persistence of diarrhœa should be followed by the prompt administration of opiates in small or moderate doses, repeated at short intervals. If there is no distinct evidence pointing to the presence of irritating bowel contents, the preliminary laxative is contra-indicated, and treatment by opium may be at once begun. If the distress is gastric rather than intestinal, an emetic dose of ipecac is a preliminary measure of undeniable advantage. In fact Briquet, Laugier, and Ollive, and quite recently Fabre, commonly employ this drug, and warmly recommend it not only in the premonitory stage of an attack, but also after the disease has actually begun.

Fabre[1] uses it even when grave phenomena already exist, provided the tongue is coated sufficiently to indicate gastric derangement. He remarks that it is surprising to witness the calm that follows the vomiting, to observe the pulse rise, a moisture bedewing the limbs, the cramps cease, the countenance lose its pinched appearance, and the general condition of the patient improve. Saline emetics are, however, universally condemned, and without sharing the sanguine views of the French writer just cited, it may yet be worthy of remembrance that when an emetic is advisable our choice should fall upon ipecacuanha in preference to other similarly acting drugs.

But to resume: A few drops of some mineral acid (nitric, or hydrochloric, but preferably sulphuric) largely diluted with water and taken frequently, may be added to the treatment by opium; not merely in the hope of destroying, as Macnamara and many others believe, "the specific cholera process going on in the intestinal canal," but because it is grateful and slightly astringent, and also for the purely empirical reason that patients have seemed to be benefited thereby.

More important, however, than the use of opiates and acids, even at this early stage, we hold to be the general regimen of the patient. He should be instructed to cease all work at once, if possible to eat and drink nothing for several hours, and to lie down either in bed or on a sofa, preferably between blankets, with a flannel bandage applied over the abdomen. A well-aired room, in which an equable temperature is maintained, should be provided for the patient's occupancy. Bland fluids, such as egg-water or mucilaginous decoctions, also soaked toast, gruels, farina, rice, may be allowed, if after about eight hours of rest and abstinence there is no return of the diarrhœa. Beef tea and all concentrated meat broths should be interdicted, even those prepared with muriatic acid. For several days following a warning of this kind, the patient should be directed to strictly regulate his diet, and carefully avoid all fatigue and nervous perturbation. Should the diarrhœa return after a number of days, he must once more fast and rest as before, and again only gradually venture on returning to his normal diet.

This simple line of treatment is the most rational as well as successful mode of dealing with the mild diarrhœal manifestations that are so frequently seen during the prevalence of an epidemic. It is true that it will not always be possible to induce, for example, an active business man to carry out measures that entail a certain amount of discomfort, and necessitate absence from his "office" for hours or even days. Yet obedience to the above advice should be strenuously urged, and in a large proportion of cases will meet with little or no opposition.

Regarding the preparations of opium, it is best to use

[1] A Treatise on Asiatic Cholera, edited and prepared by Edmund Charles Wendt, M.D., Curator and Pathologist of the St. Francis Hospital; Curator and Pathologist of the New York Infant Asylum; Member of the New York Pathological Society, of the New York Neurological Society, of the Medical Society of the County of New York, etc., etc., in association with Drs. John C. Peters, of New York; Ely McClellan, U.S.A.; John B. Hamilton, Surgeon-General U. S. Marine Hospital Service; and George M. Sternberg, U.S.A. Illustrated with maps and engravings. New York: William Wood & Company, 43-47 East Tenth Street.

[1] Traitement du Choléra. Leçons faites par le Professeur A. Fabre. Marseilles, 1884.

the tinctures, *e.g.*, laudanum or paregoric, in preference to powders, pills, or any of the alkaloids of the drug. In some cases it may be advisable to combine an astringent with the opium, but generally laudanum alone, or in strong peppermint water, is preferable to such combinations. Kino, catechu, and tannin are among the most serviceable drugs when astringents are required.

Macnamara was in the habit of distributing "cholera pills" among the well during the prevalence of an epidemic. Each pill contained a grain of opium and two grains of acetate of lead, the directions being that one be taken every hour until purging stops. It is certainly advisable in times of cholera to have bureaus, offices, factories, schools, and indeed all places where people congregate, supplied with some simple opiate, so that the first manifestations of diarrhœa may be promptly met by appropriate medication. Of course the medicine should be placed in intelligent hands, and each bottle or pill-box must be labelled with explicit directions for use.

For children and very delicate persons paregoric is preferable, as all the spices and aromatics are germicides. Laudanum, if distasteful, may be given in peppermint, or some other aromatic water, of which aq. menth. virid., aq. carui, anisi, allspice, or cloves are not to be despised. In other cases a solution of morphine in acidulated water, or in aromatic water, may be more useful and acceptable.

Dr. Fergus,[1] of Glasgow, had a number of rules drawn up and hung in prominent places of that city, during the prevalence of cholera there. They contain practical suggestions, as applicable to-day as they were then, and are therefore here reproduced, with certain changes that have suggested themselves to the editor.

1. Do not be afraid of cholera, or make it the topic of conversation. Fear and all the depressing passions are injurious.

2. Do not take brandy; it is not a preventive, and it does harm by disordering the action of the stomach and bowels.

3. Do not make any change in your usual diet, if it is simple and of easy digestion; take it moderately, and at regular intervals, as long fasting is injurious. Carefully avoid excess in any intoxicating beverage.

4. Avoid excessive fatigue. If overheated, beware of any sudden chill, and see that the skin is kept comfortably warm. If the disease appears in winter, much benefit may be derived from wearing a flannel belt round the body, covering the stomach and bowels.

5. As soon as cholera appears in a town, a bottle of acidulated solution of morphine, or laudanum, or paregoric, and a graduated measure, should be kept in every house, place of business, factory, or wherever, in fact, there are a number of people gathered together. Persons travelling should always have it with them, easy of access. During the prevalence of an epidemic, one intelligent person in each factory, etc., should take charge of the health of the inmates, acting in the *quasi*-capacity of "house-physician," and urging all under his or her care to at once attend to the slightest relaxation of the bowels. He should warn them that absence of pain does not signify absence of danger.

6. Should the slightest diarrhœa occur, the individual so attacked should receive at once the appropriate quantity marked on the bottle as corresponding to his age. The person attacked should be at once considered a patient, and conveyed home, placed in bed, and kept warm. If chilled, warm water bottles should be put to the feet. If the first dose of the "cholera mixture" has not checked the looseness, the patient should take a second after an interval of from one-half to one hour. A flannel cloth dipped in turpentine or essence of peppermint may also be placed all over the stomach and bowels for from forty minutes to an hour; or a large, soft, warm poultice of linseed meal and mustard for one or two hours. Medical assistance should be summoned if the diarrhœa has not promptly yielded. In the meantime a third and last dose of the medicine may be taken, one or two hours after the second one.

7. It is well for the patient to remain very quiet, preferably in bed, for two or three days after the diarrhœa is checked. This is to be strongly urged, for the patient often feels so well that he objects to remain in bed.

8. To relieve thirst, a piece of ice may be given, or a mouthful of iced water, or plain soda-water. In some cases even more fluid can be taken at a time; but it should then be directed by the physician. All food should be abstained from for from fifteen to eighteen hours after the medicine has been taken. Afterward the diet should for two or three days consist of such food as rice, sago, arrowroot, Indian corn flour, tea and toast, and similar bland substances. About the third day broths, chicken-soup, or beef-tea may be taken. Condiments, such as pepper, salt, cinnamon, etc., are useful. Green tea is more astringent than black.

9. *These rules are for the first stage, and for it only, namely, the diarrhœa.* If a person has neglected the first warning, and is in the second stage, having cramps, vomiting, and stools like rice-water, without smell, the patient should, until medical assistance arrives, be placed in bed between blankets and surrounded with bottles of hot water. He may receive a little ice or an occasional mouthful of cold water. The limbs may be rubbed, but not too violently, with some liniment, quickly procurable.[1] No medicine is to be given until the arrival of the doctor.

If the invasion of cholera is not preceded by the mild manifestations of simple diarrhœa, but begins at once with watery purging, the above plan may require certain modifications and additions that must necessarily again vary with the abruptness and severity of the onset. In order to insure quiet, overcome pain, and perhaps quickly influence the bowels, it is best to administer hypodermically from six to fifteen minims of Magendie's solution of morphine. If it be found desirable to maintain the action of the drug, laudanum in spice water, or paregoric, may then be used. But should the stomach prove rebellious to the laudanum, hypodermics may be from time to time repeated, the quantity being adjusted to the varying indications of the particular case, but rarely again reaching the maximum of the initial dose. Bed-rest is absolutely necessary now, and indeed, as a rule, the patient's general malaise will not incline him to disobey orders. It is advisable to place a large poultice made of equal proportions of ground mustard and flaxseed meal over the entire abdomen, and after decided reddening of the skin, replace it by ordinary poultices, opium liniment on cotton flannel, warm flannel alone, or simply a hydropathic bandage, fitting snugly but not uncomfortably around the abdomen.[2] The latter especially often gives the patient a sensation of grateful ease that it is very desirable to maintain.

Vomiting may still be absent, or, when present, it may be possible to restrain or suppress it by allowing small bits of cracked ice, cold champagne, or simple water charged with carbonic acid. Drop doses of the wine of ipecac, or one- to three grain doses of oxalate of cerium, may likewise aid in controlling the vomiting. If the patient now grows very thirsty, there is no objection to allowing him to drink plain water, that it is well to have previously boiled, then cooled, shaken, and iced. Claret or small quantities of brandy or whiskey may also be added to the water, but need not be forced upon the patient. It does not seem advisable to allow the imbibition of large quantities of liquid at one time. Small quantities given at short intervals answer much better. Any attempt to prevent collapse by using large quantities of alcoholic stimulants is decidedly reprehensible.

Small quantities of tea-punch, hot or cold, preferably hot, made of green tea, arrack, or some other nice light spirits, to which the rich can add champagne, makes a

[1] If there is time, an opium liniment may be made with one or two ounces of laudanum, one ounce of soap liniment, and an ounce or two of cologne water. It is very efficacious and agreeable.

[2] Flannels wrung out in hot cayenne pepper water are also useful.

light and digestible drink which will warm without overstimulating. Vermouth wine, which is merely a light white wine flavored with aromatic and slightly bitter herbs, is excellent. Sour and Rhine wine is better than heavy sherry, which should not only be pure, but diluted with water; ten per cent. of alcohol is as strong as any wine or diluted spirits should be used (Peters).

Although cholera patients, as a rule, crave cold fluids, it is nevertheless worthy of remembrance that, in some cases, hot weak tea, or peppermint water, or simply very hot water, is borne better than iced drinks, and may be used in place of them. In this connection it is perhaps deserving of notice that Macnamara and several other competent writers urge abstinence from all fluids. They rely solely on the use of bits of ice, allowing the patients an unlimited supply of this cooling substance. On the other hand, Macpherson,[1] from his own experience in one of the severest cases of cholera on record which recovered, says he will never deny a cholera patient a reasonable amount of water, either plain or carbonated.

Any other symptoms arising at this period call merely for cautious treatment directed toward their mitigation, but all "meddlesome interference" is very much to be deprecated. Nothing seems to the writer's mind more irrational than to attempt, by potent and varied drugs, frequently given in large quantities, combined with the use of harassing external measures, to do battle against a foe that in many cases is clearly beyond the reach of all treatment.

The following table is based on 800 cases of cholera treated in the provinces throughout England and Scotland, in 1854, and represents the percentage of failure, after the use of various remedies in premonitory diarrhœa:[1]

	Per cent.	Or, including deaths as failures.
Catechu, kino, etc	59.0	59.0
Salines	41.9	41.9
Eliminants	25.0	25.0
Calomel	34 0	25.3
Calomel and opium	18.9	22.0
Stimulants	16.0	21.8
Chalk and opium	13 8	17.1
Acetate of lead and opium	11 2	14.0
Opium	8 6	13.7
Chalk mixture	3 6	5.0
Sulphuric acid and opium	2.6	4 0

Having thus briefly outlined the simple management of premonitory diarrhœa and cholerine, we will next turn our attention to the treatment of well-marked cholera.

(To be continued.)

ABORTION IN AN HOUR.

By CHARLES H. HARRIS, M.D.,

CEDARTOWN, GA

THE difficulties encountered in the treatment of abortion are so well known that it is unnecessary to name them. The experienced physician has met with these cases in every stage of development, from the neurotic prodromata to the emptying of the uterus and its subsequent involution. Mild forms of the accident rarely come under our observation, as they transpire without exciting any alarm. Women do not take their beds for them. Indeed, it sometimes happens that they are themselves unconscious of their condition until they notice that "something has passed" from them. As a rule, it is only the bad cases that call on us—such cases as are attended with great suffering or danger. There is a reason for this tardiness on the part of the women in seeking our aid. Reduced to its last analysis, it means our objectionable management of them. We do not please them in this line of practice. The older doctors are painfully aware of this fact. They call upon us for relief, and we do what we can—perhaps tent the cervix and tampon the vagina—and tell them to be patient, that in due time everything will happen all right; or, if the case will admit of it, we rapidly dilate, curette, and extract as best we can with the usual instruments. It is this dallying conservatism and rough handling with uncertain results too well known to the women—that keep them aloof from us until they are driven in from the desperation of fear. Is it any wonder when we review the results of our work? The death-roll and wrecks of womanhood along the line of our march, justify their evasion of us, and we admire their wisdom. Along with other attractions the women have sense, and they know how to use it. Had we impressed them with our skill, things would have been different. Did they know that we could relieve them in a few moments, or at most in an hour, we would gain their confidence, and the field of accidental abortion, as yet barely touched, would be fairly ours.

That any case of abortion in which an operation is admissible may be brought to a finish in an hour, and on the first visit, I deem not only possible but eminently practicable. If we find the cervix dilated or dilatable, a few minutes will suffice. Should we find it rigid, narrow, and unyielding (a rare exception), it requires more time, patience, and perseverance to overcome this difficulty—not, however, more than an hour. This contingency is met, as we will directly understand, by means similar to obstetric forceps, and the dilatation goes on *pari passu* with the processes of detachment and expulsion. The instruments used are not forceps and dilators. They are combination curettes and snares, made expressly for the operation, and are adjustable in utero. They are of steel round wire, and flat, stout watch-spring. With little difficulty they may be made to pass the cervix of any pregnant uterus, and at the will of the operator project inside of the organ a curette or snare suited to the work. They are so slender as to practically occupy no space at all, since they become embedded in the mass of the ovum. Having observed the rules of antisepsis, the operator passes the smallest loop of snare No. 1 fairly within the uterus. This done (with average skill), he should be master of the situation. If nervous, the patient should have been chloroformed and in Sims position. His task is now almost purely mechanical, viz., to detach, chop up into small fragments, and remove the ovum. This is done by curetting and snaring. Curetting requires small loops of wire, and should be thorough and rapid. Snare No. 1 having been passed into the cavity of the uterus, its loop is now enlarged an inch (twice the size of the thumb nail) and the instrument is urged on to its work of destruction. The attachments of the placenta are rapidly severed and the staff of the snare made to sweep around the globe of the ovum. To make assurance doubly sure, enlarge the loop another inch and scrape the uterus as you would a mortar with a thin spatula. Should the membranes survive this ordeal they should now be ruptured. Draw the wires back through the staff so as to make a small loop at its terminal end in the uterus. Now aim the small loop toward the centre of the ovum and plunge it into the mass. Failing in this, Snare No. 2, with small loop, should be passed into the uterus and the membranes are easily ruptured.

A better instrument cannot be devised for this purpose. An eminent gynecologist says, "it is between a dull and sharp curette, and will take the place of both in many operations." Having ruptured the membranes, the work of snaring begins. For snaring purposes a large loop of round wire is best. A large loop of snare No. 1 is sprung in the uterus, and is kept moving until it hangs upon the ovum. Now pull with forceps movement and steadily increasing force. There will be several results from this traction. It is the best, surest, safest, and quickest way of dilating the cervix. It is a perfect uterine tampon. It will either extract entire or else divide the ovum, reducing its bulk and avoiding the necessity of

largely dilating the cervix. The finest result, however, from this traction is its remarkable effect on the uterus. Through reflex agencies beginning in the cervix contractions follow, and we invoke the best efforts at expulsion. It is this vigorous co-operation of the uterus which simulates so closely the typical abortion of a healthy woman. Should the wire cut its way through the structures of the ovum, it should be reintroduced and the snaring continued until the mass in utero is reduced to small fragments and extracted. The snares have a traction-power of over a hundred pounds, which is amply sufficient for the work.

To complete the toilet of the uterus, snare No. 2 with flat watch-spring is passed with small loop. Enlarge the loop until it presses well on the uterine wall. Pressing upward, the snare is rotated backward and forward on its terminal axis until it works smoothly. This scrapes off

Fig. 1.—Showing Snare No. 1 with Small Round Wire.

Fig. 2.—Showing Snare No. 2 with Flat Watch-spring.

the residual placenta, which, with the detritus of the ovum, is removed by passing the loop into and out of the uterus until the fragments cease to appear in it. It only remains to swab out the organ with a styptic antiseptic, and irrigate the vagina with sterilized water.

In this operation the surgeon does all the work. Nothing is left to nature or accident. It applies to the first three months of pregnancy, before the structures of the fœtus become toughened and hardened by ossification. The author is well aware of the magnitude of the task he has undertaken. Reforms in medicine are slow, and when they assume the dignity of revolution, as in this operation, they are met with bristling opposition from every quarter. It has been our purpose to place the operation for abortion where it has never been, among the certainties of surgery. Along with this we hope to capture a field of practice for the profession, which, as yet, has been barely touched. A doctor will not permit a woman to remain in labor for days without relief, and it will be equally culpable, when this operation is understood, for him to allow a case of abortion to drag its weary course along through days and weeks, as heretofore. More than this, he will be held accountable if he does not relieve his case on the first visit.

AN EXTREME CASE OF SUSPENDED ANIMATION FROM CHLOROFORM RESUSCITATED BY DIRECT INSUFFLATION IN THE INVERTED POSITION.

By A. E. PRINCE, M.D., Ph.D.,

CONSULTING OCULIST FOR WABASH RAILWAY, ILLINOIS STATE INSTITUTION FOR DEAF AND DUMB, ILLINOIS STATE INSTITUTION FOR THE BLIND, ETC.

On July 22, 1892, chloroform was administered to Mr. John P——, aged twenty-eight, for the purpose of opening the mastoid cells for a supposed abscess. The gentleman had a heart murmur, but it was believed that the administration would be unattended by especial danger, particularly as he had, within a few weeks, taken chloroform for another operation. No difficulty was at first experienced. Anæsthesia was rendered complete, and the operation was begun, but in a short time circulation and respiration were suspended, and the patient became livid.

The function of which organ failed first is not known, but, from the fact that there was no pulsation at the moment of the discovery of the arrest of breathing, and that the dark color followed so quickly, it is presumed that the case was one of heart failure; which is also rendered probable by the existence of heart lesion, which was recognized.

No time was lost in temporizing, but resort was had at once to the inverted position. The man was suspended by the flexed knees from my shoulders, and subjected to a trotting motion around the operating-room. A description of this procedure will be found in the "Transactions of the Illinois State Medical Society, 1890," and in the New York *Medical Journal*, August 22, 1891.

This inverted position, with a jolting motion, was continued while my strength lasted, after which I stood still, and my assistant practised the Sylvester method, the body being still inverted and suspended from my shoulders. No response followed, and he was placed on the table; to all appearances he was dead. The skin was blue; a hasty auscultation revealed no signs of pulsation. Hemorrhage had ceased, the last blood being of a very dark color. No time was lost, but the patient was again lifted to the shoulders of my assistant, by whom he was trotted around the room for about one minute. At this juncture the account of the infant resuscitation by blowing directly into the mouth, published by Dr. W. E Forest, in the Medical Record of April 9, 1892, entered my mind, and I called a halt, knelt down, took a deep inspiration, joined my mouth with that of the patient, and emptied the contents of my lungs into his.

The chest expanded, and the diaphragm, with the weight of the intestines, was raised, and I doubt not but that the flaccid heart was emptied of its passive blood.

Immediately the weight of the intestines and the elasticity of the chest forced a complete expiration. This was followed by another and another, until I could see that the lividity of the lips was less, though the ashen hue of the countenance persisted. A moment was taken to auscult the heart, but no sound was discerned. The artificial expansion of the lungs was resumed, and continued for about three minutes, and we noted with gratification that the color of the lips continued to improve.

An interval was allowed for auscultation, but no effort at natural pulsation or respiration was detected. Again the inflation was resumed, and continued at the rate of about twelve in the minute, for about two minutes, when the gratification was enjoyed of hearing the first natural effort at respiration.

After a little time the patient was placed on a table, and the operation finished under ether anæsthesia.

This is the sixth case of suspended functions which did not respond to either the Marshall-Hall method or the Sylvester method, the first five of which recovered under suspension treatment. Without this, I am convinced all of these would have been lost. The foregoing is the only one that did not respond to the suspension method, and I am under unutterable obligations to Dr. Forest for paving the way to the employment of the direct inflation in the inverted position of the body.

SPRINGFIELD, ILL., August 24, 1892.

REPORT OF A CASE OF EXTENSIVE PISTOL-SHOT INJURY OF BRAIN—RECOVERY.

BY O. O. COOPER, M.D.,

HINTON, W. VA.

MAY 28, 1892.—Carl H——, healthy boy, aged fourteen, was accidentally shot with a 32-calibre pistol at a distance of eighteen inches, the ball entering just above the inner canthus of the right eye and passing through the thin wall of the orbit. There was marked effusion over the right occipital region, the scalp floating from the cranium, and it was thought a fracture could be detected at this point. There was great œdema about the right eye and some about the left, but there was no ecchymosis of the conjunctiva. Pulse, 90; respiration, 18, and shallow; complete coma and left hemiplegia.

Diagnosis.—Bullet passing through right hemisphere of the cerebrum from front to rear, cutting off by the wound and the pressure of the hemorrhage most of the fibres from the motor area, and probably lodging in the occipital bone, which it fractured.

Prognosis.—Four physicians who saw the case said the injury would, without doubt, prove fatal.

Treatment.—Trephining was not done, nor was probing practised, except to introduce in the track of the bullet for two inches a strip of iodoform gauze for drainage.

Progress of the Case.—After eight hours the coma became less profound.

May 29th.—The boy could be aroused by considerable effort. Temperature, 101° F.; pulse, 100; breathing normal.

May 30th.—Fresh strip of gauze inserted. There was delirium and incontinence of urine, but the patient was able to swallow a small amount of liquid nourishment; temperature, 99½° F., above which height it did not afterward rise. Pulse, 102, rather feeble. I was able now to make out complete left hemiplegia, including the tongue and face, and complete hemianæstbesia.

June 1st.—No discharge from wound. The boy was wandering in speech.

June 3d.—Talking rationally, able to count fingers with either eye; voiding urine naturally; no elevation of temperature; complete paralysis and loss of sensation of the left side persist.

June 5th.—Pin prick felt in the left leg, but not in the arm. Effusion under the scalp greatly diminished, and a projecting body can be felt at right superior angle of the occipital bone. This was supposed to be the bullet. An incision was made under cocaine with antiseptic precautions, and the bullet extracted by using some force; the jagged splinters of its base were fastened in the skull. Several drachms of dark fluid blood escaped, after which the incision was tightly closed with catgut. The patient felt no discomfort from the operation.

June 18th.—Wounds of entrance and exit completely closed, there never having been a drop of pus in either. Sensation everywhere present, beginning motion in the left leg, none in the arm.

July 10th.—Motion in the leg is improving, and the deltoid and triceps of the arm are beginning to act.

August 28th.—Three months after the injury the boy is walking around town without a cane, using all the muscles of the thigh and leg except the antero-tibial; he is able to flex, extend, pronate, and supinate the forearm; flexes the fingers, but does not extend them; the tongue deviates to the left, the face is paralyzed on the left side; but sensation is only slightly impaired on this side; vision of both eyes is perfect; the reflexes are greatly exaggerated; the mind is clear, and there are no headaches.

Remarks.—Trephining was omitted for these reasons: The conditions were not good for a perfectly aseptic operation; the location of the bullet was by no means certain, as the effusion under scalp could have resulted from the fall after injury; it was not thought the patient would survive the operation, and it is more embarrassing to have patients die on the table in private than in hospital practice, especially with an ignorant clientele. I believe the case worth reporting. The recovery from a wound of the brain, involving the whole length of the hemisphere, and without surgical interference, is certainly unusual.

PECULIAR VASO MOTOR DISTURBANCE AFTER THE ADMINISTRATION OF PHENACETINE.

BY W. K. TINGLEY, M.D.,

NORWICH, CONN.

HAVING recently had three cases under observation where the symptoms were almost identical, I think them worthy of mention.

Mrs. E——, perfectly healthy young married woman, subject to migraine, can take phenacetine alone without symptoms or disturbance of any kind, but when champagne is taken, even after an interval of some hours, the following phenomena appear: The face becomes flushed, the eyes suffused, conjunctival vessels dilated and of a bright red color. At first the face is flushed equally, but after a time white spots appear, so that there are patches of white and red scattered irregularly over the face, neck, and chest. The head feels full, and the temporal vessels pulsate visibly, with considerable enlargement of the veins of forehead; sometimes vertigo is present, at others not. These symptoms last from two to four hours.

Mrs. C—— suffers in exactly the same manner, with the exception that the conjunctivæ are not affected.

The third case is in a young man, aged thirty, perfectly strong and healthy. If he takes champagne after phenacetine, his face becomes deeply flushed, the conjunctivæ are injected, and the head feels tense and full, with considerable vertigo. After twenty minutes or half an hour the face becomes somewhat mottled in appearance, especially on the forehead. In his case the eruption does not extend below the neck.

These cases seem to me peculiar from the fact that it is only champagne or other sparkling wine that produces the symptoms. All three of the patients can take phenacetine alone, or combined with whiskey, brandy, or claret without any discomfort, while one or two glasses of champagne starts them on this most uncomfortable round of vaso-motor disturbances.

Food Adulteration.—Ninety million dollars worth of stuff used in the adulteration of food is sold annually in the United States. At least so says a writer in the Philadelphia *Star*, who claims to have looked the matter up.

Cremation in Time of War.—The Paris Cremation Society recently addressed a petition to the French Minister of War, praying him to issue a decree making the cremation of the dead bodies of soldiers killed in battle compulsory as soon as possible after the action. The petitioners express the belief that such a measure would prevent, or at least largely mitigate, the epidemics which under present conditions are so apt to break out in countries which are the seat of war.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, September 17, 1892.

THE PATHOLOGY AND TREATMENT OF GOUT.

IT is certainly true that the English physicians bow down to and worship the uric acid crystal to an extent beyond that of other races. Cullen, to be sure, once advocated the neurosal theory of gout, and so, more recently, has Dr. Duckworth; but all the systematic English writers are thoroughly impregnated with the uric acid pathology. We are not prepared to deny that this view is the correct one; still the teachings of modern pathology lead us somewhat to doubt the possibility of an acute inflammation being set up by a deposition of uric acid crystals. Ebstein's theory, that this deposition is secondary to a local necrosis, surely deserves and has aroused attention; while recently in this country Herter has made some studies which tend to the conclusion that the uric acid deposit is an effect, or symptom, rather than a cause.

Accepting, however, the chemical and mechanical theory of gout, there could be no more interesting contribution to this subject than that furnished by Sir William Roberts in his Croonian lectures, to which we have already referred. Dr. Roberts is a firm believer in the view that gouty manifestations are the result of deposits of urates in the various joints and tissues. His concern is, therefore, to find out where and why these deposits are made. He says: "The tissues which are liable to uratic precipitations are not equally so in the different parts of the body. The cartilages, ligaments, and tendons in and about the joints, which are bathed with synovia, are much more obnoxious to these deposits than are cartilages and fibrous structures situated at a distance from joints, and which are not bathed with synovial fluid. It is further to be noted that uratic deposits favor the more superficial and cooler parts of the body, especially the upper and lower extremities, and are more rare in the deeper and warmer interior parts of the trunk. It may be inferred from these particulars that the influences which co operate to determine the site of uratic precipitations are of several and quite different kinds." One of the influences thus predisposing to uratic precipitation is the amount of sodium salts in the particular tissue, and Dr. Roberts finds that in places where the percentage of these salts is highest the precipitations oftenest occur. Thus brain has only about one-fourth the percentage of these salts as compared with cartilage and fibrous tissue, and muscle only one tenth. This difference signifies (roughly) that brain has four times more power, and muscle ten times more power, of dissolving sodium biurate than cartilage and fibrous tissue, and therefore, respectively, four and ten times more power of resisting its precipitation in their substance. It might probably be truthfully said on this ground that brain, muscle, liver, and spleen could not become the sites of uratic deposits until the connective tissues had been in this respect exhausted.

A second potent influence in causing the precipitation of urates is the synovial fluid. The connection here, according to Dr. Roberts, is very close and special. Synovial fluid has itself been repeatedly found heavily laden with crystals of sodium biurate. In the great majority of the less severe cases of gout the deposits are exclusively confined to those cartilages, ligaments, and tendons which are in actual contact with synovial sacs or synovial sheaths. With regard to the articular cartilages, it may, he thinks, be demonstrated that the uratic precipitation actually takes place from the synovial fluid, and is not self-originating in the cartilaginous substance. Vertical sections of gouty cartilages are very convincing on this point. If such sections are examined under the microscope, it is seen that the deposit hugs the synovial surface of the cartilage, and that it becomes progressively sparser and sparser toward the deeper layers, the central and deepest parts being usually quite free from deposit.

The pathology of all gouty manifestations is best explained by the lecturer on the mechanical theory alone. Joints, nerves, and other tissues are irritated by the deposits of uric acid. This explains all.

Coming to the subject of treatment, Dr. Roberts says, regarding diet: "Gouty people should be advised to partake cautiously of butcher's meat, fowl, game, and cheese, and to partake as freely as their digestion will permit of bread, rice, garden vegetables, salads, and fruit. The advantage to be gained from an adjustment of the dietary on these lines may be inconsiderable, or even inappreciable, in cases of inveterate gout, but it may be of critical moment in the slighter cases. A diminution of one or two grains per day in the amount of uric acid thrown into the circulation may make all the difference between the occurrence or non-occurrence of an arthritic attack."

As to the use of alcohol, the lecturer is conservative, but does not entirely forbid it. He advises the very moderate use of table salt. Regarding the use of alkalies, he takes a somewhat surprising position. He states that the view that in gout there is an "acid dyscrasia," and that alkalies are indicated, is "a pure assumption." He has found experimentally that the addition of carbonate of lithia or piperazine, in the proportion of 0.1 per cent. and 0.2 per cent. to blood serum or synovia, had not the slightest effect in enhancing the solvent power of these media on sodium biurate, nor the slightest effect in retarding its precipitation from serum and synovia artificially impregnated with uric acid. If these bodies have any beneficial action in gout, it is certainly not due, as has been supposed, to their solvent action on the material of gouty concretions. He advises drinking copiously of pure water (eight to ten tumblers daily), avoiding mineral waters with sodium salts. This seems to be all that is required.

INCREASED QUARANTINE FACILITIES.

While much inconvenience and suffering to quarantined passengers has been occasioned by want of accommodations for transfer, it is quite evident that the Health Officer has done his part as best he could under the circumstances. The sudden emergency has not only proved what can be done in protecting the city against a continuous and formidable invasion of disease, but has demonstrated certain defects in our present system which have never before been so strikingly manifest. In other words, the very strict manner in which the quarantine has been enforced has proportionately emphasized the necessity of increased facilities for the care of infected passengers. Unfortunately, the Health Officer, in the stern and conscientious discharge of his duty, and in the assumption of the various responsibilities which made such a task possible, has been the subject of much unmerited criticism and much unwarranted abuse. Thus, while tendering him hearty congratulations, we can consistently give him our sympathy. While keenly alive to the necessities of the occasion he was powerless to meet them, for lack of facilities in sudden emergencies. Quarantining the passengers was one thing, but transferring to places when none such were provided was quite another. The responsibilities were great, but were promptly met, and it is principally due to his energy and foresight that the quarantined passengers are even now properly cared for.

As might have been anticipated, the emergency of the occasion brought many helpers to the front, the general tendency of whom, although dictated in a proper spirit, was as much to thwart as to assist. In the midst of this grave concern for the ultimate safety of millions, the Hamburg steamers, chiefly accountable for the trouble, manifested an appalling helplessness and inexplicable apathy.

Indeed, were it not for the prompt action of the Federal Government and the Governor of the State, we would be at a loss to conjecture the extra amount of suffering which the imprisoned passengers would have been forced to endure.

The public-spirited action of Mr. Pierrepont Morgan, in promptly purchasing a steamer for the use of the sufferers, will not be forgotten by those who were the recipients of his noble generosity.

The lesson of the hour was quickly learned in the establishment of a new quarantine camp at Sandy Hook and another at Fire Island. So far we have reason to be well satisfied that the present provisions appear to be ample for any possible emergency.

The Health Officer, properly appreciating his responsibilities, called to his assistance such distinguished bacteriologists as Surgeon George M. Sternberg, of the Army, Professor Herman Biggs, of the Carnegie laboratory, and stationed Dr. Byron at Swinburne Island, also increasing his staff by such deputies as were needed. The judgment displayed in the selection has been verified in the good results of the skilled counsel thus obtained.

Offsetting this was the usual volunteered advice, which was none the less harassing though well meant. The threatened antagonism of authority in the appearance of an executive medical officer from the Marine Hospital Service, was, from many points of view, an evidence of mistaken zeal in a good cause. In one sense it was a serious reflection upon the ability of the Health Officer to discharge his duties, and in so far conflicted with the true spirit of the State law. Either the Health Officer is what he should be, or he should be removed. As it is, however, he has shown himself equal to his responsibilities, and while we must not question the good intentions which prompted the offer, we can protest against the means used to such an end. We are glad to learn, however, that matters have seemingly adjusted themselves so that the proper executive authority is centralized where it belongs. Dr. Jenkins has shown himself ready and willing to receive advice, but he must be at liberty to accept it or not, as he may deem necessary for the proper discharge of the responsible duties of his office.

THE EMANCIPATION OF THE DOCTOR.

One of the services which the medical profession of this city has done has been to emancipate its members from many of the needless and narrowing conventionalities of the past. There was a time when a doctor had to set himself apart; he was obliged to wear a black coat, a professional air, and refrain from dancing and all other social frivolities.

Not long ago, says the *Sun*, a Boston physician of eminence wondered how the New York doctors could dare to go to their clubs during the day. If he were seen entering the Somerset Club in Boston in broad daylight, he said, his practice would suffer disastrously. Under such stress the doctor was obliged to carry his profession everywhere with him; he could be a doctor and nothing more. In Washington, and probably other cities, the physicians dare not be seen riding a bicycle or doing anything else savoring of ordinary human enjoyments. This city has certainly, more than any other, broken loose from this thraldom. The doctor has to study harder, work harder, be more alert and wise and skilful than ever. But if he is known to be thus industrious and skilful, he is allowed as much personal freedom as any one. The change is vastly for the better. The time is going by when "a good bedside manner" is the essential thing. The physician now must, above all things, understand his profession, and know how to deal with human nature. True, he can ride a bicycle, wear a sack-coat, russet shoes, and go to a club, if he is rich enough for such luxuries.

THE NEW CURE FOR NEURASTHENIA.

It has been found in France, and the sheep furnishes it. Our interesting congener, the pig, who has been doing wonders in a peptic way for the neurasthenic's stomach, now has a rival that is forced to give its head to nervous exhaustion. Gray matter from the sheep's brain is cut into bits, macerated, put into five times its weight of glycerine, and subjected to other process, all of which is detailed in the *Bulletin del'Académie de Médicine*, No. 7, 1892, until a filtrate is produced for injection into the abdomen of the nervously weak. About seventy-five drops of the filtrate, which is called "nervous matter," constitutes a dose. And the method of treatment is known as nervous transfusion. One Constantin Paul discovered it, and "tranfused" eleven persons with sterilized ten per

cent. solution of gray matter from the sheep's brain, without abscess or pustular acne supervening. In all these cases there was either cure or great improvement. Three were classic neurasthenics, three others neurasthenic chlorotics, one was a case of chronic bradycardia, and four suffered from locomotor ataxia. Muscular weakness rapidly disappeared under this treatment; pain and sensitiveness in the back grew less; headache, insomnia, functional brain weakness, were all exorcised after few or many injections of the new filtrate. This nervous matter must certainly be taken with a grain of salt to aid osmosis. Meantime, discoverers like Brown-Séquard and Constantin Paul deserve one good opinion of great value to themselves—namely, their own.

THE TREATMENT OF HEART-FAILURE FROM CHLOROFORM.

The *International Medical Magazine*, July, 1892, quoting from a German journal, gives Maass's description of a method in use at the Göttingen Clinic by which the heart can be made to resume its action after apparently fatal paralysis from chloroform. Rapid impulses are given to the region of the heart by the hand of the surgeon, as many as one hundred and twenty a minute. The operator stands at the left side of the patient, laying his right hand on the left side of the chest and placing the ball of the thumb half-way between the apex beat and the sternum. The left hand is applied to the right side of the chest and steadies. The rapid compressing motions are made with the right hand. Two patients have been revived by this method perseveringly applied for half an hour or more, after their restoration seemed hopeless. Heart contractions ceased whenever compression was interrupted, though shallow respirations continued spontaneously.

CHOLERA AND QUARANTINE.

That cholera appears in New York simply proves that the strictest quarantine cannot always guarantee safety. While we may have good reason to be satisfied with results up to the present we must recollect that in spite of the best of systems the dreaded disease may surreptitiously find an entrance into the city. It is unnecessary to allude to the many ways by which this may be accomplished. We have before referred to the different avenues through which the city may be approached other than by those of quarantine.

In cases of invasion it is natural to blame the health officer. Before doing so it would be well to examine thoroughly into the history of the first cases, and see where the responsibility truly rests. Very often the pestilence sows its seed before its appearance in infected ports is reported and the necessity for quarantine is made apparent. All these conditions have to be considered in explaining the fact that quarantine, as ordinarily enforced, fails in about seventy per cent. and succeeds only in thirty.

A Corner on Vaccine was brought about recently in Moscow, and in view of a threatened epidemic of small-pox the price of the virus was increased some thousand per cent.

News of the Week.

Cholera in New York.—On Wednesday of this week it was officially declared by the Health Department that Asiatic cholera was present in New York. There were five deaths. The first case occurred September 6th, and the last on Tuesday. The announcement was delayed until a positive diagnosis was made by the discovery of the comma bacillus in the dejecta. The health authorities have as yet no definite knowledge of the way in which the plague entered the city. The infected houses have been properly quarantined since the first appearance of suspicious symptoms in the cases.

Cholera in India.—A correspondent of the *British Medical Journal*, July 9, 1892, writing from Srinagar under date June 11th, states that the epidemic there began on May 6th, and that there had been over eight thousand cases and five thousand deaths in Srinagar alone, out of a population of one hundred and twenty-four thousand, and at least fifteen hundred deaths in the district. Srinagar is one of the filthiest of cities, has neither drains nor latrines, nor any real system of conservancy. Arrangements have already been made to introduce a pure and protected water supply. Advantage will be taken of the recent destructive fire to rebuild the burnt-out area on sanitary lines, and efforts are being made to introduce a proper system of conservancy.

The Number of Deaths from Cholera in Russia, up to September 1st, has been officially placed at about one hundred and sixty thousand. Adding to this upward of forty thousand deaths in other parts of the Continent, we obtain a total of two hundred thousand victims in Europe alone There is no doubt that these figures are much below the actual number, for the official returns are universally acknowledged to be incorrect. How many have perished in Central Asia will never be known.

In Hamburg the epidemic is reported to be decreasing, and people are beginning to appear again in the streets and to frequent the cafés. There is, however, a terrible amount of suffering among the poorer classes. Commerce has been almost entirely suspended, and, in consequence, great numbers of laboring men have been thrown out of employment, and unless relief is quickly furnished it is feared that there will be rioting in the city.

The Port of Colon, on the Isthmus, has been closed against all vessels from Europe, and also from any other place where cholera may exist. It is not known whether the authorities there will look upon New York as an infected port or not.

Precautions Against Cholera in Boston.—The City Board of Health has taken active measures to prevent the importation of cholera and to take charge of it should it appear. The Mayor has recommended a twenty days' quarantine for all vessels carrying steerage passengers, sailing later than September 5th. Additional accommodations have been built on Gallop's Island, and other islands in the harbor will be occupied by the Board of Health, should it be necessary. Several buildings in the city have been selected and placed in condition to be made into temporary hospitals at short notice. All

immigrants, on arrival at quarantine, are given a bath, and their clothes and baggage are disinfected by steam.

The New York Academy of Medicine, at a special meeting held Monday, September 13th, passed a resolution that a committee, consisting of Drs. A. L. Loomis, A. Jacobi, E. G. Janeway, Stephen Smith, R. H. Derby, T. M. Prudden, and Allan McLane Hamilton, should examine into the methods of quarantine in the harbor of New York and report upon the same at a future meeting of the Academy.

Sir Joseph Fayrer, if the cable reports him correctly, doesn't think much of the views held by the rest of the medical world concerning cholera. He says that the diffusion of human intercourse does not explain the movements of epidemics, and he holds that, whatever the true origin and cause of cholera may be, the materies morbi is diffused through the atmosphere rather than in water. Nevertheless, he is willing to yield to a popular prejudice so far as to admit that, "it is undeniable that bad sanitation, and especially impure water, invites and increases the severity of cholera when the epidemic is present in the atmosphere." Of course, holding such views, he thoroughly disapproves of quarantine.

Quarantine on the St. Lawrence.—The Provincial Government of Quebec has issued a proclamation giving full force of law to the resolutions recently adopted by the Central Health Board. The resolution provides that no passengers shall be permitted to land from infected ports in any part of the Province, and that no immigrants at all, no matter where hailing from, are to be landed there. Regarding the vessels with passengers aboard which have already sailed for the St. Lawrence, an arrangement has been made by which the immigrants will be landed after undergoing whatever disinfection and examination in quarantine may be deemed necessary by the Board of Health.

Costa Rica has closed her ports against all immigrants from Europe until after the subsidence of the cholera. Several parties of agriculturists had been formed to establish colonies in that country, and this prohibition of immigration will cause great inconvenience.

To Investigate the Hamburg Officials.—A Berlin despatch to the *Staats-Zeitung* says that a discussion will be opened shortly in the Bundesrath upon the conduct of the city officials and police of Hamburg in relation to the present epidemic.

The Spanish Authorities have ordered that all vessels coming from London be subjected to quarantine in Spanish ports. The Consul of Spain in New York has refused to give clean bills of health to vessels sailing from this port.

The Russian Hospitals.—Professor Virchow has recently visited Russia, and reports that the means in use for combating the cholera in that country can hardly be improved upon in any respect. This report is so at variance with what other observers have said, that the German physicians are wondering how many cholera hospitals Virchow's hosts permitted him to inspect.

Section on Public Health of the New York Academy of Medicine.—Stated Meeting will be held on Monday, September 19th, at 8 P.M., when the following papers will be read: "The Present Status of Quarantine Laws, with their Administration," by S. T. Armstrong, M.D.; "How Long shall a Cholera-infected Vessel be Detained at Quarantine?" by A. L. Carroll, M.D.; "General Disinfection: Steam, Sulphur, Sublimate," etc., by J. H. Raymond, M.D.; "The Biological Characters of the Cholera Spirillum," by George M. Sternberg, M.D., Deputy Surgeon-General U. S. A.; "Local Measures of Prevention and Relief in New York City," by Stephen Smith, M.D.; "The Profession and Cholera—Suggestions," by A. Jacobi, M.D. Remarks by Dr. E. G. Janeway, the Chairman, and others. Henry D. Chapin, M.D., Chairman; S. T. Armstrong, M.D., Secretary. The profession is cordially invited to attend.

American Gynecological Society.—The Seventeenth Annual Meeting will be held in the chapel of the Polytechnic Institute, Livingston Street, near Court, Brooklyn, N. Y., on September 20, 21, and 22, 1892. Physicians are cordially invited to be present.

Drawing the Line at Cholera.—The peasants of a little village near Moscow, fearing an invasion of cholera, put a charm around the place in accordance with an old superstition. Six virgins, led by two widows, dragged a plough at midnight around the village, while a third widow preceded them, carrying in her hands a banner with the image of the Holy Virgin. The cholera, as the peasants believe, will never be able to cross the line made by the plough, and as long as they remain within this magic circle no harm can come to them from this scourge.

A Large Placenta.—Dr. C. C. Perry, of West Rutland, Vt., writes that he assisted at a case of childbirth recently, in which the placenta weighed $4\frac{3}{4}$ pounds. It was apparently normal in other respects.

A Slight Error.—The New York correspondent of the London *Lancet* informs the readers of that journal that there were 1,663 deaths from measles in this city during the past year. The writer made the mistake of getting his figures at second hand, and so credited us with 1,000 deaths too many.

A Big Price for Typhus.—A man named Herskowitz has sued the proprietors of a Bowery lodging-house for $10,000. He says that in February last the Health Board removed from the house several persons afflicted with typhus fever, and that he took a room there subsequently under representations that there was no danger of the fever. He contracted the fever, and from February 20th to May 13th was on Ward's Island. This is at the rate of $1,000 a week.

A Day in Bed once every month is the prescription which Dr. F. W. Abbott suggests, in the *Massachusetts Medical Journal*, for the overworked physician. It will do him more good, the writer says, than an annual vacation several weeks in length.

Colony System for the Insane in France.—The "family" system of treating lunatics, which has been so successfully carried out in Belgium, at Gheel, and more recently at Lierneux, and also in Scotland and in the United States, has not till quite lately found favor in France. At the instigation of M. Charles Féré, however, the General Council of the Seine Department instituted in 1891 an inquiry on the subject. As the result of this

inquiry the Council, at a meeting held on July 12th, adopted a report presented by M. Deschamps, in which a proposal was made that a first "family colony" of one hundred patients suffering from senile dementia, and belonging exclusively to the category of harmless lunatics, shall be established at Dun-sur-Auron, in the Cher Department.—*British Medical Journal.*

Attempted Suicide of Children.—Five children in Berlin recently attempted to commit suicide in order to escape cruel treatment at the hands of their stepmother. One only of the children died The oldest of the five was but thirteen years of age.

Garbage Disposal in Montreal.—The Board of Aldermen of Montreal has accepted a plan for the cremation of garbage, and work is to be begun immediately upon the construction of two incinerators just outside of the city.

A Stereotyped Verdict.—Coroner's juries in England are becoming so familiar of late with deaths from chloroform that they have learned to give them the euphemistic name of "death from misadventure," and such is the verdict brought in in nearly every case wherever occurring.

Medical Education in Hyderabad.—Dr. Lawrie, the Director of the Medical Service of Hyderabad, gives an account of the progress of medical education there. He says that there are now eighty-five students in the Medical School, and among those who were graduated during the year were three women.

An English Physician has recently been threatened with prosecution for attending his own mother in a Swiss hotel. "It is lamentable," to quote our sorrowing contemporary, *The Lancet*, "to think how illiberal the law of Switzerland is in reference to foreign medical men."

Female Medical Students in Edinburgh.—The Governors of the Edinburgh Royal Infirmary have yielded to pressure and have agreed to admit female students to two wards, containing about twenty beds each. The University requires a minimum of eighty beds for medico-chirurgical teaching, but it is hoped to get over this objection by admitting women to the eye and skin departments. In commenting on this permission so reluctantly given, the *Medical Press* says that "the Governors may as well give in with a good grace. They have surrendered all the principles upon which they opposed the admission of the ladies, and they need not haggle about the throwing of the sponge to the full height. They will have to follow the British Medical Association, tied to the victorious chariot of the ladies."

The British Army Surgeon has a sore grievance against the Duke of St. Albans. In a recent magazine article on one of the tropical colonies, his grace mentioned incidentally that a military doctor, having mistaken one case of yellow fever for delirium tremens, proceeded to treat subsequent cases of "drink" as yellow fever, in order to avoid the repetition of the error. The noble duke probably meant it for a joke, but he forgot that he was writing for British readers, and until they "catch on" he must suffer for his imprudence.

Legislating against Itinerant Quacks.—The city of Effingham, Ill., enjoys the privilege of having a physician for mayor, and its City Council has recently passed the following ordinance: Be it ordained by the City Council of the city of Effingham: That it shall be unlawful for any itinerant physician or itinerant vendor of drugs or medicines to practise medicine in any of its branches, or sell or dispose of any drug, medicine, nostrum, or ointment intended for the treatment of disease or injury, or to open an office for such purpose, or to announce to the public in any way an intention to practise medicine, or to sell or dispose of such drug, medicine, nostrum, or ointment within the corporate limits of this city. Provided, That nothing in this ordinance shall be so construed as to prohibit any reputable physician or surgeon from any other place being called to see a particular case or family, or to do a particular operation in said city. Any person violating this ordinance shall be subject to a penalty of not less than fifty ($50) dollars nor more than one hundred ($100) dollars.

Dated this 2d day of August, A.D. 1892.

Approved: J. B. WALKER, *Mayor.*

Attest: W. M. STEWART, *Clerk.*

Laudanum without Opium.—Three druggists in Nottingham, England, were recently fined for selling adulterated laudanum. In two cases the liquid contained a very small quantity of opium, but in one there was not a trace.

American Association of Obstetricians and Gynecologists.—The following is the list of papers to be read at the fifth annual meeting of this Association, to be held in St. Louis, September 20, 21, and 22, 1892: "Posture in Relation to Obstetrics and Gynecology," by Dr. Wm. W. Potter, of Buffalo; "Nephrotomy and Nephrectomy Successfully Performed on One Patient for Multiple Abscess," by Dr. Geo. S. Peck, of Youngstown; "Present Status of Obstetrics, with a Report of My Own Work," by Dr. Joseph Price, of Philadelphia; "The Essential Question of Drainage in Pelvic Surgery," by Dr. L. S. McMurtry, of Louisville; "The Intestinal Canal as a Source of Infection in Abdominal Surgery," by Dr. W. G. Macdonald, of Albany; "The Technique of Vaginal Hysterectomy," by Dr. J. H. Carstens, of Detroit; "The Repair of Intestinal Lesions which occur during the Progress of Abdominal Operations," by Dr. W. E. B. Davis, of Birmingham; "The Surgical Treatment of Intestinal Wounds," by Dr. David Barrow, of Lexington; "Tetanus Following Minor Gynecological Operations," by Dr. Edwin Walker, of Evansville; "Advantages of Version in a Certain Class of Obstetric Cases," by Dr. A. P. Clarke, of Cambridge; "The Pelvic Symphyses in Pregnancy and Parturition," by Dr. W. J. Conklin, of Dayton; "Embryotomy," by Dr. E. P. Bernardy, of Philadelphia; "The Delivery of the After-coming Head," by Dr. W. W. Seymour," of Troy; "Tumors of the Abdominal Wall," by Dr. Edward J. Ill, of Newark; "Two Unusual Cases of Fibroids: Removal by Abdominal Section," by Dr. A. B. Miller, of Syracuse; President's Address: "Some Considerations in Reference to Uterine Hemorrhage—Puerperal and Non puerperal," by Dr. A. Vander Veer, of Albany; "Sacral Resection: Its Place in Pelvic Surgery," by Dr. E. E. Montgomery, of Philadelphia; "Clinical Report of Gall-bladder Operations," by Dr. R. B. Hall, of Cincinnati; "Is Evolution Trying to do Away with the Clitoris?" by Dr. R T. Morris, of

New York; "The Surgical Treatment of Cancer of the Uterus," by Dr. C. A. L. Reed, of Cincinnati; "Abdominal Hysterectomy," by Dr. Joseph Price, of Philadelphia; "Abdominal Fixation," by Dr. F. Krug, of New York; "Experiences in Abdominal Surgery on the Insane," by Dr. W. P. Manton, of Detroit; "The Relation of Pelvic Disease and Psychical Disturbances in Women," by Dr. Geo. H. Rohe, of Catonsville; "Pus in the Pelvis and Abdomen: Its Diagnosis and Treatment," by Dr. Joseph Hoffman, of Philadelphia; "Plastic Surgery of the Genital Tract," by Dr. T. E. McArdle, of Washington; "Plastic Surgery of the Pelvic Structures," by Dr. H. O. Marcy, of Boston; "Abdominal Section for Diagnosis," by Dr. Clinton Cushing, of San Francisco; "Extra-uterine Pregnancy," by Dr. Edwin Ricketts, of Cincinnati; "Four Cases of Ectopic Pregnancy and the Lessons they Teach," by Dr. R. B. Hall, of Cincinnati; "Ectopic Gestation: Its Varieties, Symptoms, and Treatment during its Several Stages," by Dr. J. F. W. Ross, of Toronto.

Bedbugs, according to Dr. Dewèvre, may be the carriers of tuberculosis contagion. His attention was called to this possibility by a case of tuberculosis occurring in a young man who slept in a bed formerly occupied by his brother, who had died of the disease. The room had been thoroughly disinfected, but the bedstead had for some reason escaped this salutary process. Dr. Dewèvre observed that the young man had been bitten by the insects, and securing some of them, found them full of tubercle bacilli. He afterward put some presumably healthy bugs in contact with tuberculous sputum, and was able to obtain from them, several weeks later, some excellent cultures of tubercle bacilli. The bugs seemed lively, however, and had no cough, night-sweats, or other of the familiar clinical symptoms of the disease.

The American Electro-therapeutic Association will meet at the Academy of Medicine, New York, October 4th, 5th, and 6th. There will be discussions upon "The Relative Fœticidal Value of the Different Currents and their Application to Ectopic Gestation," and "Cataphoresis and its Practical Application as a Therapeutic Measure." Papers are announced by Drs. George J. Engleman, Wellington Adams, and George F. Hulbert, of St. Louis; William F. Hutchinson, of Providence, R. I.; Franklin H. Martin, of Chicago, Ill.; A. Lapthorn Smith, of Montreal; R. J. Nunn, of Savannah, Ga.; Thomas W. Poole, of Lindsay, Ontario; C. Eugene Riggs, of St. Paul; W. J. Herdman, of Ann Arbor, Mich.; D. S. Campbell, of Detroit, Mich.; G. Betton Massey, of Philadelphia; Henry D. Fry, of Washington, D. C.; H. E. Hayd, of Buffalo, N. Y.; J. H. Kellog, of Battle Creek, Mich.; C. G. Cannaday, of Roanoke, Va.; Ernest Wende, of Buffalo, N. Y.; and William J. Morton, Augustin H. Goelet, A. D. Rockwell, Landon Carter Gray, Robert Newman, Ephraim Cutter, Frederick Peterson, J. Mount Bleyer, G. M. Hammond, and F. Van Raitz, of New York.

Orchid Tea.—The Parisians have recently been developing a taste for a new beverage called Faham tea. This is a product obtained from the flat dried leaves of a small species of orchid (*Angræcum fragrans*) with white flowers, which grows as a parasite hanging from trees in the forests of Mauritius and Réunion. Although the plant in question has been long known to botanists and the beverage used locally, its introduction to Paris as an article of commerce is quite recent. Samples of this "orchid tea," and of cigars made of the leaves, which emit a vanilla-like aroma, according to the *Kew Bulletin*, are now deposited in the Museum, and the plant can be seen growing in the orchid house. The tea is very simply made by putting the leaves in cold water, about fifteen grains to the teacupful, closing the vessel and boiling for ten minutes. The tea may be sweetened according to the taste, and milk and rum bring out the flavor more strongly. It is as good cold as hot, and may be warmed up without deterioration. Material enough for fifty cups is sold in Paris for 2 fr. 50 c.

Father Mollinger's Remedies.—Since the death of Father Mollinger the shrine on Troy Hill has been closed, and the good Saint Anthony is enjoying a holiday from the miracle business, but the profits arising from the trade were too large to be given up without effort, and we have the druggist who prepared the priest's prescriptions advertising "Father Mollinger's Remedies" for the cure of cancer, consumption, rheumatism, etc. But it seems he is not to have this lucrative field without rivalry, for the private secretary of the deceased clergyman is announcing "The Only True Remedies of Father Mollinger," and claiming that his official position gives assurance of the genuineness of his preparations. These remedies, it seems, are the stock prescriptions which the reverend Father was wont to give with his blessing, and it may be assumed that he apportioned them according to what ability he possessed as a medical man. Now they are to be used for self-treatment by the people at large. Truly, "The evil that men do lives after them, the good is oft interred with their bones." With the reputation among the vulgar that Father Mollinger possessed, comes a grand opportunity for a successful quack medicine establishment, and we would recommend the occasion to the enterprising gentlemen of St. Louis who are so prominent and apt in this business.—*Pittsburgh Medical Review.*

A Hydrophobia Scare.—Between ten and fifteen persons were bitten a few days ago, in Anderson, Ind., by dogs supposed to be suffering from rabies. One person is said to have died from hydrophobia, and all those bitten are suffering from fright.

Dr. John J. Reese, of Philadelphia, died on September 4th, at Atlantic City. He was born in 1818, and was graduated from the University of Pennsylvania in 1839. During the war he served as Assistant Surgeon in the army. For twenty-five years Dr. Reese occupied the chair of medical jurisprudence and toxicology at the University of Pennsylvania, and was a well-known writer and authority on these subjects.

University of Edinburgh.—The number of medical degrees conferred at the recent commencement at Edinburgh University was the largest on record, including 202 Bachelors of Medicine, and 60 Doctors of Medicine.

The Russian Congress of Hygiene will be held in St. Petersburg, in the spring of 1893, under the protectorship of the Grand Duke Paul Alexandrovitch. The work of the Congress will be divided into five sections, namely: 1. Biology. 2. Sanitary and Medical Statistics, Epidemi-

ology, and Medical Geography. 3. Hygiene of Inhabited Districts, Public and Private Buildings and Work-places, Food Supply, Clothing, Cleanliness and Disinfection, Hospital Administration, and other Prophylactic Measures. 4. Hygiene of Rearing and Education. 5. Geology, Climatology, and Balneology.

L.R.C.P. & S.Ed.L.F.P. & S.G.F.R.C.S.Ed. are the letters following the name of a Professor of Anatomy in one of the medical schools of this great country. He ought to be a good one.

Sir Walter Foster enjoys the distinction of being the first member of the medical profession to have a position in the British Ministry, having accepted, under Gladstone, the post of Political Secretary to the local Government Board.

An Epidemic of Typhoid Fever.—According to a recent despatch typhoid fever is prevailing to an unusual extent in the town of Oakdale, near Pittsburg. There were, a week ago, over one hundred and twenty cases under treatment and the mortality was about eighteen per cent. The water supply is said to be in a wretched condition.

Laryngology at the Rome Congress.—It had been arranged by the Organizing Committee of the Eleventh International Medical Congress that laryngology and otology should be combined in one section. Dr. Fraenkel, President of the Berlin Laryngological Society, protested so energetically against this decision, however, that it has now been determined that each of these sub jects shall have a section to itself.

Cremation in England.—The first incineration in the newly erected crematorium at Manchester took place on August 22d. The body was that of Mr. Thomas Morgan Brown, who died at Carlisle at the age of eighty four years. He had recently returned to England after a residence of forty years in this country.

An Army Medical Board will be in session in New York during October, 1892, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Regulation of the Ice Supply.—The Conseil d'Hygiène de la Seine, recognizing the possible dangers from cholera and other germs, have forbidden ice to be taken from certain ponds and have passed resolutions controlling the quality of ice sold in Paris. The Prefect of Police has been requested to supervise the manufacture of artificial table-waters, and to inquire into the purity of waters used in making artificial ice.

The University of Bonn.—Professor Sämisch has been elected Rector of the University of Bonn, and Professor Binz Dean of the Medical Faculty.

Influenza is reported to be raging in Peru. In some parts almost half the inhabitants are attacked by the disease.

Dr. Albrecht Burckhardt has been appointed to the newly founded Chair of Hygiene in the University of Basle.

The Academy of Medicine of Lima was recently asked by the government for an opinion as to the value of registration and examination of prostitutes in the prevention of syphilis. The committee to whom the question was referred was unanimous in its approval of the proposed measure.

Foot-ball Casualties.—Eleven deaths and seventy severe injuries resulted from foot ball playing in England during the past season.

A Piece of Steel in the Heart.—A man died a few days ago in Brooklyn from the results of a fracture of the skull received in a bar room fight. At the autopsy a piece of steel wire, looking something like a woman's hatpin, nearly an inch and a half long, was found in the heart-wall. The point at which it entered the body was found in the form of a minute scar just below the left nipple. How long it had been in the heart could not be determined, but it was evidently not of recent introduction.

The Health of Panama.—Dr. C. H. Williamson, writing to the *Sanitarian* from Panama, says that for some time that city has been quite healthy, and not a case of malignant fever has been heard of in several months. No doubt, he says, its causes still exist, but the reduction of the population has diminished the *materies morbi*. The sanitary condition of the city has been somewhat improved; many of the streets have been repaved and are regularly swept by the prisoners from the jail; several small plazas have been renovated and inclosed by iron railings, the walks cemented, seats provided, trees and plants set out, so that they now present quite an ornamental and pretty appearance. Panama is, however, destitute of a proper system of sewerage and an adequate supply of water, and until these defects are remedied it must continue to be liable to disease, particularly in the dry season.

The Medical Pioneer is the name of a new journal to be published monthly in London by the Council of the British Medical Temperance Association.

Chicago Physicians have, as it appears to outside barbarians, the strange custom of herding together in the tall down-town buildings. Thus it is said that in the Venetian building on Washington Street over six hundred doctors have their offices, while the Masonic Temple comes in a good second with five hundred and seventy.

Hiccough is often arrested by red pepper tea taken as hot as possible.

Tape-worm has been successfully treated by salicylic acid in hourly doses of eight grains each. After the fifth dose castor-oil is given.

London Specialists.—Dr. William E. Briggs, writing from London to the *Occidental Medical Times*, is rather severe on certain of the physicians of that town who are known as specialists in various branches. For example, he says: "A number of men who have done much for ophthalmology in London have died during the past fifteen years, and among their successors there is no one conspicuous as a scientist, original investigator, teacher, or operator. In the throat hospitals one sees some good work, but of the treatment of the ear the less said the better."

Canadian Militia Surgeons.—A special general meeting of the Association of Medical Officers of the Militia of Canada will be held during the session of the Canadian Medical Association at Ottawa, on September 21st, 22d, and 23d.

Correspondence.

OUR BERLIN LETTER.

(From our Berlin Correspondent.)

THE ONLY USE FOR BACTERIOLOGICAL AMBITION—CHOLERA IN GERMANY—SALOL AS A REMEDY—IMMUNITY AGAINST CHOLERA—EXTERMINATION OF FIELD-MOUSE—DEATH OF PROFESSOR VON MEYER.

BERLIN, August 23, 1892.

THE annual vacation for physicians, commencing at the beginning of August, terminated abruptly owing to the dread of the cholera spreading from the East.

Until a few days ago the conditions of health on the "border line" between Germany and Russia were satisfactory. With the exception of a single case of "cholerine" in Breslau, and sporadic cases in the northern Schlesingen districts, the health reports, considering the hot summer, were excellent.

Unfortunately, however, cholera has forced its way through Hamburg, which is the most dangerous medium for its transmission through Germany. To-day we have authentic cases of Asiatic cholera in Altona and Hamburg. The Government sent Professors Koch and Rahts to Hamburg to use all sanitary precautions which they thought advisable. The mortality thus far is about fifty per cent. Considering the position of Hamburg, its enormous shipping, the unsatisfactory sewerage, it is but a question of time when cholera will push its way into the centre of Germany. Luckily we are ready to meet this pest in the hospital Moabit (barracks), which is destined to be used as an epidemic hospital. In all other large hospitals the building of barracks which are all isolated has been commenced.

As the cure of cholera is still a grave desideratum, so our main point will be "prohibition methods." This is the only practical use for bacteriological ambition, and it remains to be seen whether the prophylactic promises will be fulfilled. It will be very interesting to watch for the first time the combined prophylactic apparatus against a disease which has been thoroughly mastered from a bacteriological point of view. As the pest progresses innumerable new remedies are suggested, many of them very ridiculous.

The most important for us are the recommendations of Professor Loewenthal, in Paris, and Professor Rosenbach, of Breslau. Dr. Loewenthal reports that Dr. Francisco J. Gonzales y Salvador, in Yba (Philippine Islands), has tried salol in fifty-three cases and cured all but three of his patients. As against a mortality formerly of forty-five per cent., the latter's mortality in the salol treatment was six per cent. As early as 1888, Loewenthal recommended salol after experimenting in Berlin, in Koch's institute, partly also with Cornil, in Paris, owing to the fact that salol on entering the system forms salicylic acid and phenol; not only killing the bacteria but preventing the formation of the cholera poison.

Although we do not dispute the brilliant results of Dr. Francisco J. Gonzales y Salvador, we believe that salol will share the same fate as the other antiseptics, reacting only in test-tubes or on guinea-pigs! The next practical point is the recommendation of Rosenbach, owing to the fact that C. Fränkel found that carbonic acid gas retards the growth of cultures of cholera bacilli. It is therefore indicated in the treatment of cholera to introduce carbonic acid gas into the stomach and intestines.

Rosenbach has tried this method for a long time for other purposes, and has demonstrated the fact that it is not dangerous. The only antagonism that would be encountered is first the pylorus, and then the Bauhin valve, which might prevent the entrance of gas into the small intestines. This may be overcome by consequent use of opium.

Alongside of these direct treatments we have investigators trying to render the body immune against cholera. Two such have been proposed, one by Dr. Klemperer, who is known by his experiments of immunity in pneumonia, who has tried to inoculate animals with cholera cultures (weakened by heat), and has produced immunity by direct injections of weakened cultures from 40.5° to 70° F., as also by injecting the serum of such immune animals. It is also interesting to note the experiment of prophylactic inoculation against the cholera intoxication from the intestine.

In reality the author was able, by using intra-peritoneal injections of heated cultures, to save animals which had previously received a deadly dose of cholera. Another experiment of the same author was to introduce a smaller dose of cholera cultures (not fatal) into the stomach, and after they recovered to inject the absolutely deadly dose. The author found that three days after introducing into the stomach from 5 to 8 c.c. of a cholera culture previously heated for two hours at a temperature of 70° F., that the animals were positively poison-proof (gift festigkeit). Animals receiving such treatment could withstand the deadly dose of either an intra-peritoneal injection or the introduction of the poison into the stomach. It must be mentioned that immunity was only rendered when, previous to introducing the immunity culture, he introduced 5 c.c. of soda.

Animals not receiving the soda died in the same manner as the control animals.

Opium injections combined with the soda prior to the immunity rendering injections, were useless. Animals treated with soda only, and then with the heated cultures, were all saved.

He also was able to render immune animals which had been injected with cultures through which an electric current had been passed.

The method of Brieger and Wasserman is based on the principle which these investigators, combined with Kitasato, reported a few months ago in the *Magazine for Hygiene for Infectious Diseases*, vol. xv., p. 137.

The investigators allowed cholera bacilli to grow twenty-four hours on a thymus culture, after which it was heated fifteen minutes at a temperature of 65° F., or ten minutes at a temperature of 80° F., and the so-prepared culture allowed to remain twenty-four hours in the ice-box. As a rule, guinea-pigs received .4 c.c. of this fluid (intra-peritoneal injections) on four succeeding days. The animals developed fever, partly subnormal temperatures, and recovered the following day.

On repeating these injections the same type of symptoms developed in a milder degree. Animals receiving this treatment could stand, four to five days after the beginning of this treatment, three times the deadly dose of the cholera culture. The animals merely reacted with a slight increase in temperature. The minimum dose to arrive at a poison proof condition was 1 c.c. of the above-named culture given on two succeeding days.

As the thymus fluid is rather difficult to obtain, these investigators tried to grow the cholera vibriones in the ordinary meat, water, peptone, gelatine, and heated these cultures on the following day for fifteen minutes to 65° F. With these cultures they were able to render guinea-pigs poison-proof against the cholera culture. The smallest poison-proof dose was 2 c.c. In order to test whether the heat was an important factor in rendering these cultures poison-proof, these investigators took cholera cultures on "thymus fluid" and stood them on ice a few days. With this fluid they produced the same poison-proof as they could with the heated, proving that the specific action exists in the thymus gland.

In the last number of *Centralblatt für Bacteriologie*, Professor Löffler, in Greifswald, a prominent scholar of Koch, reports the successful extermination of the field-mouse with the bacillus of mouse-typhus This bacillus is one of the recent additions to bacteriology. The important advantage of this bacillus, and which proved useful in the extermination of the field-mouse, is the fact

that when introduced into the digestive apparatus house- and field-mice are positively killed; whereas sheep and goats remain unharmed. That human beings are affected is out of the question. An important point was found by Löffler in the course of his experiments, that when inoculating one mouse in a certain cage, that all mice in this cage were infected from this inoculated mouse. The transmission occurs because the healthy mice are fed with the dejecta of the infected mice, which always contain bacilli, and swallow the deadly substance with the food.

The habit of mice to lick dead mice is a reason for the transmission of the mouse-typhus. Especially are mice fond of eating the intestine and brain of mice succumbing to mouse typhus.

After these investigations Löffler recommended the bacillus of mouse-typhus. The first opportunity to test the efficacy of this treatment Löffler received through a recommendation from Pasteur, when a commission, consisting of officers and landowners, begged him to apply his method to exterminate mice in Thessaly. Löffler tried, with brilliant result, the following method:

He laid small pieces of bread impregnated with mouse-typhus in small holes, hoping that the mice would swallow these and infect themselves. The transmission would result, he thought, by the swallowing of dejecta of the primary infected animals, and by licking of the dead from mouse-typhus. This method which Löffler planned proved fruitless. It was a question whether field mice in the middle of spring would eat bread when they had plenty of greens. In its practical execution the method was as follows: He was well stocked with clear cultures. He then prepared culture fluid. He boiled oats and straw with peptone and grape-sugar. He impregnated bread by laying it into dishes containing culture fluids. The pieces of bread were then placed into the mouse-holes. After one week a considerable reduction in the number of mice could be noticed. Of the successful result after his return Löffler was informed by the Grecian Government.

On July 21st Professor Heman v. Meyer, aged seventy-seven, died. He was one of our most prominent anatomists. His scientific career was based on the investigations of the mechanics of the human system. Professor v. Meyer was, from 1844 to 1889, professor in Zürich. He succeeded Jacob Henle, who at that time accepted a position at Heidelberg. Since 1889 Meyer has lived in his birthplace, in Frankfort-on-the-Main. His successor is Professor Phillip Stöhr, formerly of Würtzburg.

FEMALE PHYSICIANS IN INSANE ASYLUMS.

To the Editor of the Medical Record.

Sir: In an editorial in the Medical Record of August 20th, concerning female physicians in insane hospitals, it would appear that, at least in one State, the medical profession has come to recognize the propriety and advantageousness of the employment of women physicians for the care of the insane of their own sex: The resolutions adopted by the Pennsylvania Medical Society are in themselves a strong argument in favor of the movement, which the editor of the Medical Record takes occasion every now and then to condemn. Coming as they do from the profession of a State where women have been successfully tried in this capacity, shows that the need has not been over-estimated and that women physicians have proven their qualifications and abilities to be nowise inferior to those of male physicians.

The editor says: "Sometimes a female physician is needed and is useful." Medical people, at least, know that the causes of insanity, the habits, manners, and therapeutic requirements of the insane are practically the same the world over, and if a woman is needed and is useful in one hospital she is in another. The fact that "there are lady medicals who neither adorn nor help this ill-illumined world" has no more to do with the question than that there are gentlemen (?) medicals of whom the whole profession are ashamed, and who could not get a position on a hospital staff if they tried ever so hard. This class of either sex is not wanted in any position about an insane asylum.

Many unprejudiced superintendents are willing to acknowledge the reasonableness of the demand, and voluntarily employ a woman physician. In a personal letter, a hospital superintendent of twenty years' experience, speaking of his institution, says: "In a hospital where insane women are confined I think it eminently appropriate that they should receive the advantage of being treated by a physician of their own sex." But this matter should not be left to the discretion of superintendents, as they are frequently changed, and are often whimsically prejudiced. If it is wise and just and fitting that women should administer professionally to insane women, then it should be made compulsory by an act of legislation, and not left to the option of anyone. The State does not construct and maintain hospitals for the specific purpose of giving superintendents an opportunity to display any special predilection toward one sex or the other in the selection of their medical staff.

The comfort and welfare of the patients are supposed to receive some slight consideration.

Sara A. Kime, M.D.

Fort Dodge, Ia. August 18, 1892.

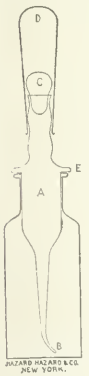
New Instruments.

AN INSTRUMENT FOR SYRINGING OUT CORTICAL MATTER IN CATARACT EXTRACTION.[1]

By JOSEPH A. ANDREWS, M.D.,

NEW YORK.

The accompanying cut represents a simple apparatus for syringing out cortical matter after cataract extraction.



Reduced one-half in size.

A is a hollow ground stopper drawn out into a tube which terminates in a smooth point, B, 1 mm. in diameter and curved as shown in the cut. The rubber nipple D serves to draw up and inject the fluid contained in the bottle. The ground stopper C closes the hollow stopper A, and prevents the fluid in the bottle from becoming contaminated by contact with the rubber nipple D when the bottle is transported. The collar E protects the mouth of the bottle from dust, etc.

The instruments in use for removing cortical matter in cataract extraction are either some sort of apparatus on the principle of the fountain syringe, with rubber tubing attached, or a very small hypodermic syringe (Meyer's). It is evidently not a simple matter to keep rubber tubing attached to such an apparatus aseptic, except by some such fluid as a solution of corrosive sublimate; and this, we know, is an objectionable injection for the anterior chamber of the eye. The same objection applies to the hypodermic syringe used for this purpose. The apparatus figured in this sketch is, therefore, simply a half-ounce bottle with a hollow stopper drawn out into a tube. The fluid used need never, if ordinary care be observed, pass up beyond the stopper C; therefore it comes in contact with glass only, which is readily sterilized by heat. The apparatus enables us to use a simple inoffensive fluid, as distilled water and one-half of one per cent. of chloride of sodium, which has, of course, been previously sterilized by heat, and which answers completely the purpose for which it is intended, *i. e.*, the mechanical re-

[1] Presented at the Twenty-eighth Annual Meeting of the American Ophthalmological Society, New London, Conn., July 19, 1892.

moval of cortical matter from the anterior chamber of the eye. It is almost needless to mention that the injection of air-bubbles into the eye can readily be avoided by withdrawing the tube from the anterior chamber before the last drops of fluid have been injected. These bottles are also used for washing out the conjunctival cul-de-sac preparatory to cataract extraction, and for such solutions (atropine, eserine, cocaine, etc.) as are required in cataract extraction. These bottles are made by Hazard, Hazard & Co., New York.

9 West Twenty-second Street.

Progress of Medical Science.

Auto-Infection of Cancer.—Dr. Hamburger relates an instance of auto infection of cancer. The patient was a woman who had an ulcerating epithelioma on the left labium minus. A number of small warty growths appeared upon the opposite labium which had come into contact with the somewhat acrid and offensive discharge from the original tumor. The growths upon both sides were removed and proven by microscopic examination to be all flat-celled epitheliomata.—*Med. Chirurg. Records*, No. 12, 1892.

Jejunostomy by a New Method.—In two cases of carcinoma Dr. Maydel (*Wiener Med. Woch.* No. 20, 1892), has operated by a new method, after finding that the greater curvature of the stomach and adjacent parts were so implicated that total extirpation or gastro-enterostomy was out of the question. A section of intestine below the duodeno-jejunal fold was drawn through the incision and the fæces well pressed out. It was then encircled with strips of iodoform gauze, to prevent further entrance of fecal matter, and cut across. An incision was now made on the surface of the distal portion about half an inch in length, just opposite the attachment of the mesentery, and into this opening was sutured the cut end of the proximal portion. The mucous surfaces were first united carefully, and then the serous surfaces were securely sutured with a double row of sutures. The still open extremity of the distal portion of the intestine was now united to the abdominal wound, and through this fistulous opening nourishment was maintained. Recovery followed promptly in both instances.

Sciatica and Varicose Veins.—Dr. Quénu expresses the opinion that certain cases of sciatica are due to varicose veins. He states that in people with varicose veins and sciatica, varicose veins are found around the nerve and sometimes adherent to it. A patient who had tried various other measures without success obtained relief for two years by wearing an elastic stocking up to the groin. In two other cases in which the pain had been intolerable Quénu dissected the veins away from the nerve. The pain disappeared, and has been absent for fourteen months in the one case and four or five months in the other more recently operated on. He looks on the operation of stretching the nerve as a brutal procedure, giving by no means brilliant results.—*The British Medical Journal*, June 11, 1892.

Non-bacillary Phthisis.—In a lecture on fibroid phthisis delivered at the London Hospital, Sir Andrew Clark said, among other things: "It has been alleged by Koch—and it is generally believed in London—that every case of phthisis, as I have defined it, is microbic, is associated with and dependent upon the presence and the action of tubercle bacilli. For my own part I presume to deny the allegation and to contend that while the great majority of cases of phthisis are bacillary there is a considerable minority of cases which are non-bacillary, in which at no period of their history can bacilli be found. To this denial it is sometimes replied that if the bacilli were not there when you sought for them they were there when you did not, or if they were very enthusiastic and proportionately polite they will say that you were unable to find them and that they were certainly there. Some years ago I had in my own wards three cases of what I designated as non-bacillary fibroid phthisis. I invited two or three of my more distinguished contemporaries to examine these cases and to demonstrate the existence of the tubercle bacillus in them. They failed and, justifying their failure, said, 'These are quite exceptional cases and do not break down our generalization.' But, gentlemen, it is just the exceptional cases of this kind that demand the most careful consideration, for although they do not bear immediately or greatly upon our practical clinical teaching, they bear sufficiently upon it to justify me in calling your attention to it at this time."

Death Under Pental.—The death of a German opera-singer is reported by the *British Medical Journal*, July 9, 1892, to have recently occurred after the administration of pental for the extraction of a tooth. Eight or ten drops were given upon a face-piece and the tooth removed, whereupon the patient fell back with a loud shriek and never recovered consciousness, attempts to restore animation proving of no avail. The official examination showed that the brain, lungs, and vessels were healthy; there was, however, some amount of fatty degeneration of the heart, and death was attributed to syncope, probably due to the condition of that organ.

Creosote in Tracheotomy.—Dr. Soupault reports, in the *Rev. des Mal de l'Enfance*, September, 1891, favorably upon the internal use of creosote in full doses after tracheotomy, and attributes the excellent showing of four to six per cent. of recoveries to its use. The drug is also to be applied externally over the tube in a one to thirty solution in alcohol and glycerine.

Gum-lancing.—Dr. Wood is convinced that gum-lancing is a highly important method of treating various conditions in childhood. He has seen convulsions, restlessness, disordered stomach, fever, and many functional disturbances immediately cured by this means, after various other measures had failed. Since amaurosis and many other conditions in the adult are well-known results of the trigeminal irritation from faulty teeth, it is only natural to expect more frequent and more severe troubles from the same variety of irritation in the child. The benefit is not to be attributed to the local extraction of blood, or to the relief afforded the inflamed gum, but to the removal of the backward pressure upon an extraordinarily sensitive and congested nerve-pulp. It is essential that the operation be thorough, and the dense tissues which bind down the teeth be completely divided.—*University Medical Magazine.*

Rule for Controlling the Sex.—Dr. Keefe gives the following in the *New York Medical Journal*, July 2, 1892: "When a given couple are having an excess of girls, and it is desired to have boys, they must refrain from all sexual intercourse, the female must wean her child, and live almost continuously out of doors, having gentle exercise, but not carried to the point of fatigue. She must be relieved of all, or nearly all, of her household cares, have a good rich diet of milk, rare-done meat, wine, fruit in moderation, amusements, and everything calculated to promote cheerful and happy thoughts. Her husband must have a more sparse diet and hard work. When male children are in excess, this treatment, except the paragraph referring to lactation, may be applied to the husband. Referring to animals, I would apply the rule in the same manner, and in addition would allow the male, if the stronger, to have connection with other animals while the female out of which it is desired to breed a male is resting."

Hemorrhage by Suggestion.—Drs. Artigalas and Rémond have published a case (*Revue de l'hypnotisme*, February, 1892) of a girl, who at sixteen had for some time daily nose-bleed. At the age of twenty-one hysterical attacks were noted, followed by vomiting of blood, and

subsequently hemorrhage from the left ear. Some days later there was bleeding from the left eye, and for several days in succession there were tears of blood and hysterical stygmata, hemianæsthesia in right side, and diminished sensibility of the pharynx. It was suggested that the blood cease to flow from the eye and escape by way of the hand, whereupon the palm began to show a bloody sweat, and this was arrested by suggestion that the whole process stop.

Syphilis Occulta is the name given by Dr. Fleiner to the late manifestations where the patient has no knowledge of when or how the disease was contracted, and in whom no evidence exists of early symptoms—the primary and secondary signs having been absent, or so slight as not to attract attention. It is apt to be severe because of non-treatment. The distinction between syphilis hereditaria tarda and syphilis occulta is that the former is congenital. It is not proper to assume, in the case of those who show tertiary symptoms at the age of fifteen or twenty, without previous history, that the disease is always hereditary. It must be remembered that it may be an instance of syphilis acquired in infancy which has remained hidden or occult, especially as children are exposed in many ways to infection.—*Deutsch. Archiv für Klin. Med.*, No. 48.

Albuminuria in Epilepsy.—From the observations of Drs. Voisin and Péron, albumin is found in the urine in about half the cases after the attack, and the quantity is in proportion to the number of seizures. The presence of albuminuria can thus not aid in differentiation between epilepsy and eclampsia. It has been noted that when the fit is attended with cyanosis and marked congestion of the face the quantity of albumin found is comparatively large.—*Archiv. de Neur.*, May, 1892.

Treatment of Actinomycosis.—Actinomycosis has generally been considered, in man at least, an almost incurable, if not a hopeless disease. Dr. Raffer, in the *Riforma Medicale* of February 4th, has reported four cases of recovery, in which the disease was accessible to surgical measures. These were scraping and the injection of antiseptics into the tumors—these injections consisting of a five per cent. solution of carbolic acid in glycerine, and if sinuses were present, cotton wool saturated with this fluid was introduced into them. Veterinary surgeons have for a long time employed tincture of iodine with much success as a local application, but quite recently a very distinguished teacher at the Utrecht Veterinary School has drawn attention to the value of iodide of potassium in every form of the disease when given as a drug; from his experience of this agent in cattle affected with actinomycosis, he pronounces it an infallible remedy, and Professor Nocard, at a recent meeting of the Paris Central Veterinary Society, in giving an interesting account of the disease, mentioned instances to prove that this medicament promptly and radically cures actinomycotic glossitis in cases which were formerly deemed hopeless. The dose for the ox began with six grammes in half a pint of water once a day to commence with, soon increased to eight grammes, until signs of iodism began to manifest themselves, when it was continued for a few days longer.—*The Lancet*, July 9, 1892.

Permanganate of Potash in Blennorrhagia.—Professor Reverdin employs a 1 to 5,000 solution of permanganate of potash in blennorrhagia, introduced by means of a small catheter passed down to the bulb, and the urethra thoroughly irrigated with about a quart of the fluid, at the temperature of 100° F., twice daily. A cure can be effected, it is said, in from three days to two weeks, and usually in a week's time, without any internal medicine.—*The Provincial Medical Journal*, August 1, 1892.

Therapeutics of Uric Acid Gravel.—Sir William Roberts, in a series of lectures on the chemistry and therapeutics of uric acid gravel and gout (*Lancet*, June 25, 1892), says the treatment of calculous disorders must be in the main preventive. The chemical force which is requisite to prevent the precipitation of uric acid in the urinary channels is almost infinitely small as compared with the force which is requisite to redissolve a concretion already formed. Uric acid gravel is constantly seen existing *per se*, in persons who are in all other respects perfectly healthy. From a therapeutic point it is a mischievous notion that uric acid gravel and gout are substantially the same disease. Gravel should be regarded as a primary vice of the urinary function, and the urine the proper field for its investigation and treatment. The author's experiments point strongly to the suggestion that subjects of gravel should be advised to take as much culinary salt as their palates will tolerate. The most reliable investigations indicate that fat, sugar, and starchy matters have not the slightest influence on the production and excretion of uric acid, nor has any proof been given that albuminoid substances of vegetable origin differ in this respect from albuminoid substances of animal origin. The author believes that the free use of farinaceous articles, salads, fruit, and garden vegetables, all comparitively poor in albuminoid constituents, should be advised. All other schemes of treatment sink into insignificance in comparison with that of diminishing the acidity of the urine. It is chemically impossible for uric acid to be deposited from an alkaline urine, and as we have the means of harmlessly reducing the acidity of the urine at will, we have in our hands, in principle at least, the absolute power of preventing uric acid gravel. The risk in gravel is almost confined to precipitations which take place within the precincts of the kidneys, and the author has found that the most risk of precipitation in the kidneys is during the time of sleep. Therefore, a single dose of citrate or bicarbonate of potash or soda (forty-five to sixty grains dissolved in three or four ounces of water), taken at bed-time, suffices for the milder cases. In others, a second dose can be taken in the night when the patient has a call to empty the bladder. The precipitation can thus be postponed until the urine reaches the bladder, whence it is swept away, as a rule, before it has a chance to do harm.

Tetanus.—Drs. Valliard and Ronget, in a report of their recent observations upon tetanus, *Annales de l'Institut Pasteur*, June, 1892, state that pus taken from the original injury in tetanus always contains numerous microbes in addition to the bacilli of tetanus which act by attracting leucocytes. Inoculation of tetanus from animal to animal soon fails completely, owing to the ease with which the auxiliary bacilli lose their power of developing in the tissues. This would account for the difficulty with which the affection spreads. So called idiopathic tetanus is due to a previous infective injury. Spores may be introduced, and though engulfed by leucocytes, may escape rapid destruction, and any departure from health (such as a bruise, chill, etc.) turns the scale in favor of the spore. Large wounds are less often followed by tetanus than small ones, probably because they are more carefully and rapidly treated with antiseptics.

Cool Baths in Typhoid.—Dr. Juhel-Rénoy believes that the introduction of the cool bath into the hospital treatment of typhoid fever has reduced the mortality at least five per cent., and cites figures in support of his opinion.

Treatment of Tricophytosis Capitis.—Dr. Laënnec washes the scalp with a solution of corrosive sublimate (1 to 4,000). The patches are then well soaped, scraped, and washed again and the lather reapplied. The following ointment is then spread over the entire scalp :

℞ Acid. chrysophanic.,
Acid. boric.,
Acid. salicylic.....āā gram 2
Vaseline..... 100

A rubber cap is now put on, which serves the additional purpose of protecting the eyes. The ointment is reap-

plied on the second day, and replaced on the third by frictions with essence of turpentine alternating with those of corrosive sublimate, after which the ointment may again be applied.—*Gaz. Méd. de Nantes.*

A Contribution to the Study of Hepatic Abscess.—Dr. Dabney (*The American Journal of the Medical Sciences*, August, 1892) bases a paper upon the analysis of one hundred and eight cases collected from various sources, and draws the following conclusions: 1. That hepatic abscesses rarely occur as a result of injuries or diseases of the bones or other parts of the body, except those directly connected with the portal system of veins, or immediately adjacent to the liver. 2. Ulceration of the bowels is a common cause of hepatic abscess, but neither the morbid changes nor the symptoms are those of simple dysentery. It is probable that in most cases, at least, when the hepatic abscess is due to dysentery the latter disease is amœbic in character. 3. An hepatic abscess may appear in two weeks from the commencement of the dysenteric attack, but the usual time is from four to twelve weeks. It is impossible to say how long a time must elapse after an attack of dysentery before all danger of hepatic abscess is past. 4. Abscesses originating in the bile-ducts, and those due to injuries of the liver itself, seem to be of comparatively rare occurrence. When due to injury, the abscess usually appears in a few days. 5. Abscesses occurring in connection with general septicæmia or pyæmia are probably nearly always multiple in number and small in size, but in rather more than half of all other cases the abscess is single and comparatively large. Abscesses due to gall-stones, however, are usually multiple. 6. Aspiration occasionally fails to reveal an hepatic abscess, because the needle may not enter it, or the contents of the abscess may be too thick to flow through the needle. 7. There are no means of determining with certainty the presence or absence of adhesions in a given case; pain, tenderness, and œdema over the seat of the liver suggest the presence of adhesions, but are by no means certain proof of their existence. Even the up-and-down movement during respiration of a needle inserted into the liver, is not a conclusive proof that adhesions do not exist, as was shown by a case recently under my care. 8. Of the symptoms and signs of hepatic abscess, pain, tenderness, and swelling in the hepatic region are by far the most important. Fever is present in a large proportion of cases, is intermittent in character, and except in pyæmic cases rarely rises above 102.5° or 103° F. Jaundice and ascites nearly always denote the presence of dense adhesions or gall-stones. Dyspnœa and cough are frequently present. 9. It is doubtful whether absorption of the contents of an hepatic abscess ever occurs; bursting is of frequent occurrence, the most usual direction being into a bronchus or the pleural cavity. Under expectant treatment death occurs in a large proportion of cases before bursting. 10. With respect to treatment, free incision and drainage give far better results than any other mode. The results of aspiration are rarely satisfactory, nor is aspiration itself entirely free from danger.

Searching for Light from Another Realm.—The lecturer on theosophy had concluded his long and able address, and stood looking at the audience. "If there is any question," he said, "that any of you would like to ask me before I sit down, I should be pleased to answer it." Amid the deep silence that followed this remark, an earnest-looking man near the door rose up and said: "I'd like to know, Professor, if anybody has ever yet discovered a reliable and certain cure for warts?"

He May have Died of the Antidote.—A man in Wilkesbarre, while picking wild berries on the mountain, was bitten by a rattlesnake and died a few hours later. In the effort to save his life six quarts of whiskey were poured down his throat.

Therapeutic Hints.

Tuberculous Bronchitis.—The following is recommended for the cough in commencing pulmonary phthisis:

℞. Creosote ..... ℥ j.
Tincture of cinchona ..... ℥ j.
Chloroform ..... ℥ ss.
Malaga wine ..... ℥ xij.

A dessertspoonful before each meal in a little water.

Salol in Chronic Cystitis.—Dr. E. Mansel Sympson, writing in *The Practitioner*, vol. xlviii., No. 6, 1892, recommends salol very highly in the treatment of chronic cystitis. As the drug is insoluble in water, he gives it in the following mixture:

℞. Salol ..... ℥ ij.
Pulv. acaciæ ..... q. s.
Aq. cinnamomi ..... ad ℥ xij.

M. et ft. mistura. Sig.: A tablespoonful every four or six hours.

Urticaria.—According to the *College and Clinical Record*, Dr. Stelwagon recommends the following local application for the relief of urticaria:

℞. Acidi carbolici ..... ℥ ij.
Acidi borici ..... ℥ iv.
Glycerini ..... ℥ j
Alcoholis ..... ℥ ij.
Aquæ ..... ad Oj.

M.

The systemic treatment should be the removal of the cause. Any disturbance of digestion must be corrected, if possible, and the diet should be of a simple character.

Summer Diarrhœa.—The Paris correspondent of the *Medical Press* sends to his paper the following formula for a remedy for summer diarrhœa:

℞. Lactic acid ..... ℥ ij.
Syrup of lemons ..... ℥ iv.
Water ..... ℥ xxxiij.

M. Sig.: To be taken during the day.

Gallacetophenone has been recommended in the treatment of psoriasis. It is applied in the form of a ten per cent. ointment.

A Depilatory.—The *Bulletin of Pharmacy* suggests the following as a good depilatory:

℞. Barii sulphidi ..... ℥ j.
Amyli,
Zinci oxidi ..... āā ℥ ss.
Aquæ ..... q. s.

M. et ft. Pasta.

This is to be spread evenly and not too thickly over the part and scraped off within ten minutes, or earlier, if pain is felt.

Europhen in Burns.—A writer in *La France Médicale* speaks enthusiastically of an ointment containing europhen as an application for burns. The following is a serviceable formula:

℞. Europhen ..... gr. xlv.
Olive-oil ..... ℥ ij.
Vaseline ..... ℥ ij.
Lanolin ..... ℥ j.

M. Sig.: For external use.

Quinine Hypodermically.—Dr. S. R. Hodge, writing in the *China Medical Missionary Journal*, gives the following formula for Waller's solution of quinine for hypodermic use:

℞. Quiniæ bisulph.,
Acid. tartaric ..... āā ℥ ij.
Glycerine ..... ℥ j.
Aquæ ..... ad ℥ ss.

Place the quinine in the bottom of a large wide-mouthed test-tube, put the heavier tartaric acid on top of it, add the water, heat gently to boiling-point over a spirit-lamp till a clear solution results, stirring it with a glass rod from time to time; then as it cools add the glycerine.

A clear one-ounce solution by measure results, of which dr. j. contains gr. xv. of quinine, and of course ♏ xx. = gr. v. This latter dose is equal to gr. xx. of quinine given by the mouth.

Asthma.—A writer in the *Gazzetta degli Ospitali* recommends a mixture of equal parts of lobelia, stramonium, and green tea leaves, rolled into a cigarette, for the relief of asthma. The leaves are well mixed and then soaked for a time in a saturated solution of potassium nitrate. After this they are dried and then kept for use in a large-mouthed, well-stoppered bottle.

Chapped Hands.—Dr. Steffen uses the following for rough and chapped hands:

℞. Menthol ..... gr. xxv.
Salol ..... ʒ ss.
Olive oil ..... ♏ xxv.
Lanoline ..... ʒ x.
M.

When this ointment is applied twice a day, the pain quickly ceases, the skin softens, and the rhagades heal.

Rheumatic Pains.—Rhus toxicodendron is recommended by several writers in the *American Therapeutist* as particularly efficacious in sciatica and other forms of neuralgia occurring in individuals with a rheumatic tendency.

Creosote is now prescribed so frequently for so many affections of the stomach and lungs that a Vienna pharmacist serves it from his soda fountain, and has numerous customers for it. The following is the formula for the syrup:

℞. Creosote ..... 1 part.
Cognac brandy ..... 50 parts.
Simple syrup ..... 300 parts.
Tincture of peppermint ..... 2 parts.
Mix.

—*Medical and Surgical Reporter.*

Summer Diarrhœa.—The following is one of an infinite number of formulæ recommended in this affection:

℞. Zinci oxidi ..... ʒ j.
Sodii bicarbonatis ..... ʒ ss.
Tinct. kameriæ ..... ʒ ss.
Syr. chloroformi ..... ʒ iij.
Aqua ..... ʒ ij.
M. Sig.: A tablespoonful every half hour.

A Skin Tonic.—The following is said to be an excellent cosmetic wash for the face:

Spirit of ammonia, and
Spirit of camphor, each ..... 1 ounce.
Coarse salt ..... 2½ ounces.
Boiling water ..... 1 pint.

These are thoroughly mixed, and when the solution is cold three ounces of alcohol should be added. It is to be well shaken before being used.

Exophthalmic Goitre.—Dr. Dieulafoy, writing in the *Bulletin Médical*, says that in cases of exophthalmic goitre the aim of treatment should be to lower the vascular excitement. He compares patients with this affection to those threatened with pulmonary hemorrhage, and treats them in the same way. He gives from four to six pills a day, made according to the following formula:

℞. Pulv. ipecac ..... gr. vj.
Pulv. digitalis ..... gr. iv.
Ext. opii ..... gr. ss.
M. et. ft. pil. No. xij.

He has had several cases in which an apparent cure resulted in the course of a few months. The only inconvenience of this medication is an occasional diarrhœa, which may be very troublesome until a tolerance has been established.

Anaphrodisiac Effect of Cocaine.—Dr. C. L. Gregory calls attention in the *American Therapeutist* to a loss of virility, amounting even to impotence, which he has observed in a number of cases to follow repeated applications of cocaine to the nasal mucous membrane.

For a Red Nose.—For the relief of redness of the nose not due to alcoholism an exchange recommends the local use of a five per cent. aqueous solution of boracic acid.

Tonic after a Debauch.—Dr. Whitla says that the following is of service in cases in which insomnia, anorexia, loss of will power, and mild hallucinations, following a prolonged debauch, point to threatening delirium tremens:

℞. Quininæ sulphatis ..... gr. xxv.
Acidi nitrohydrochlor. dil. ..... ʒ vi.
Ext. cinchonæ ..... ʒ iij.
Aquæ destillatæ ..... q. s. ad ʒ x.
M. Sig.: A tablespoonful in water three times a day before meals.

Treatment of Spinal Abscess.—Dr. Burrell concludes as follows concerning the management of abscesses in Pott's disease: 1. Efficient mechanical support of the spine is the prime factor in the treatment of caries of the spine associated with an abscess. 2. Under an expectant plan of treatment the abscess will, in many cases, disappear. 3. The indication for operative interference is a steady or rapid decline in the patient's general condition. 4. The operation should consist in thorough evacuation of the abscess, and the establishment of drainage from as near the seat of the disease as is practicable. —*Archives of Pediatrics.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 10, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	56	11
Scarlet fever	64	3
Cerebro-spinal meningitis	0	3
Measles	48	12
Diphtheria	71	17
Small-pox	5	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Sanitary Progress in Washington.—With the first of July the city adopted the system of carrying off garbage in patent air-tight steel carts, and, treating it with exhaust steam, to pass the offensive gases into the sewers (in other words, into the houses and streets). "The plan works well, and we are delighted," says a correspondent. It must be delightful.—*Sanitary Era.*

For Sea-sickness.—Dr. John M. Miller, writing in the *British Medical Journal*, says that a four years' experience at sea has convinced him that there is no remedy like Worcester sauce, in teaspoonful doses, given without water, for preventing and curing sea-sickness. In some cases the good effects of the remedy may be increased by the application of a tightly applied bandage, rest on the right side, and frequent small quantities of fluid food. The remedy is easily obtained on most steamers, pleasant to take, and has often succeeded in the writer's hands when all other means have failed. It should be given every three hours until the stomach can tolerate and retain ordinary food. He does not approve of stimulants, but gives small quantities of good beef-tea with cayenne pepper in it.

Vaccination and Small-pox.—It is a noteworthy fact that not a single case of small-pox occurred during the year 1890 in the British army. If this be not evidence of the protection afforded by re-vaccination against a malady once so common—and still disastrously fatal in

armies where this precaution is not vigorously enforced—then logic and reason are mere accomplishments!—*Medical Press.*

Cows.—The late Sir James Simpson once discomfited a cross examining counsel by saying that, for the purpose of his argument, a cow was as good as a countess. The physiological equality of human and bovine females is also officially recognized in the department of the Rhône, as appears from a circular recently sent to the medical inspector of the district, in which a reference is made to the necessity of increased facilities for the analysis of "samples of the milk of women, cows, or other [animals]" (*femmes, vaches, ou autres*). This reminds us of an advertisement which used to be—and, for all we know, still is—issued by a large shipping firm, in which the catalogue of the virtues and attractions of their vessels wound up with the announcement that they carried "an experienced surgeon and a cow."—*British Medical Journal.*

Rheumatism in Japan.—It is a strange fact, mentioned by Dr. Michaut, of Yokohama, that in spite of its being an essentially moist and rainy country rheumatism in all its forms is a pathological rarity among the natives of Japan, while the Europeans residing there are almost all rheumatic. This immunity the writer is inclined to attribute to the use of very hot baths, which is universal in Japan. The temperature of the Japanese bath is never less than 107° F., and he has been assured that they can endure a bath at the temperature of 122° F. A Japanese bathes once, sometimes twice, a day. His skin is more active than that of Europeans, is thicker and much less sensitive to cold and to external irritations.—*Boston Medical and Surgical Journal.*

Good Bread.—The Russian Public Health Society is about to establish a few model bakehouses in St. Petersburg, where all kinds of bread will be procurable free from adulteration and at reasonable prices.

Medical Work in Berlin.—The *British Medical Journal* summarizes in a recent number the statistical report of the Clinical Institute of the Berlin University for the year 1891-92. According to this report, v. Bergmann's surgical clinic received 1,717 patients, of whom 156 died, and 1,532 were dismissed after treatment. In the outpatient department 20,818 persons were treated. Professor Senator's policlinic treated 12,379 persons, and Professor Schweigger's eye policlinic 11,688 persons, and 1,095 persons were received as in-patients. In Olshausen's Gynecological Institute there were 1,082 births, and 876 further patients were received. In the policlinic attached to the Institute 2,501 obstetrical cases and 1,078 other cases were treated; 381 gynecological operations were undertaken, and there were 150 post-mortem examinations, of which 60 were new-born infants. The Ear Hospital received 248 in-patients; and 25,648 were treated in the policlinic attached to it; 2,953 cases were treated in the policlinic for throat and nose diseases, conducted by Professor B. Fraenkel.

Excellent Advice.—"Doctor, Wash your Feet," is the title of an article in one of our Chicago contemporaries.

Medicine and Morals.—Diderot has said that there is scarcely one moral maxim which may not serve also as a medical aphorism, and, on the other hand, there are very few medical aphorisms which cannot readily be converted into moral maxims.

Mosquitoes in Fleet Street.—London has recently been aroused to an unwonted pitch of excitement over the appearance of a few mosquitoes in town, and the papers are full of prescriptions for keeping them away from the sleeper. Even *The Lancet* joins each week in the general chorus, gravely recounting the virtues of various more or less disagreeable face-washes and the like. "Yet one other contrivance," it says, "even more easy of use because automatic, might be mentioned. This consists in the familiar practice of suspending some rather pungent antiseptic, such as carbolic acid or eucalyptus, in a vessel over a small gas-jet, lamp, or candle, so that the fumes may impregnate the air of apartments which are all too close to accommodate both men and mosquitoes. Human endurance may well sustain the feather-weight of such trifling impedimenta, and even enjoy the incense of unwonted odors when they bring deliverance from an acquaintanceship as trying as it is unhappily seasonable." Have our cousins ever heard of mosquito-nets?

An Italian Medical Novelist.—Dr. Leonzio Capparelli, who died in March last, in Naples, was a well known physician of that city, and was also the author of several works on medicine and surgery. Five years ago he published a novel entitled "Dr. Pietra," which attracted considerable attention and met with a very favorable reception from both critics and the public. Since his death his daughter has found among his papers the manuscript of another story, called "In Illo Tempore," which she has edited and will have published in Florence. The plot is laid in the slums of Naples during the reign of the notorious Bomba, and is said to be full of interest, as well as realistic in the better sense. At the same time with this, a new edition of "Dr. Pietra," containing all the author's changes of the original, will be published.

Orificial Surgery in a Nutshell.—Dr. Carmichael thus explains it all in the *Medical Times*: "In these days of a more perfected knowledge of the nervous mysteries of the body, there is no difficulty in tracing the translation of such morbid irritations all through the endless mazes of the nervous tendrils, winding here, there, and everywhere, through an unbroken continuity, onward and upward in this case, through vaginal, uterine, and ovarian sympathetic plexuses by cell antennæ to ganglia; again, still onward and upward through hemorrhoidal and sacral plexuses to afferent nerves, to columns of cord, to medulla oblongata, to central, cerebellar, and cerebral ganglia. Finally, by tendrils of corona radiata and association fibres to the cortex of the brain, the efficient factor of mentality and intellection, all ending in the deplorable overthrow of the mind and the development of insanity. Thus in few words we have before us the details of the sad and sorry picture, and thus do we bring into bold relief the beneficent effects of 'Orificial Surgery.'"

Where Salubrity is Not.—Dr. Salmons, writing to the *Indiana Medical Journal* from Guanajnato, Mexico, says that with two more deaths a month that town would have a death-rate of one hundred and thirty to the thousand, or six times as great as that of the largest cities of civilized countries. The city has forty thousand inhabitants. Most of the deaths were among the very lowest classes, who live in utter disregard of hygiene. Forty-two per cent. of all the deaths in May were of children under one year old, and from two-thirds to three-fourths were caused by diseases of the alimentary and respiratory organs. Of these two classes of diseases there were three times as many cases of the former as of the latter. There were many deaths from small-pox, but the health officer did not even think it worth while to call attention to it, an evidence that, large as the death-rate then was, the disease was not unusually prominent. Dr. Salmons adds, parenthetically, that he has a large practice. There certainly seems to be a field there.

Nursing Knows no Creeds, even as sickness makes no distinction for color, class, or sex. Again and again, in these columns, while we have maintained that the best nurse will be the woman who closely follows in the footsteps of the Great Physician, we have equally argued that dogmas and sects have no place in the sick room or the hospital ward. We have strongly disapproved, on the one hand, of the narrow bigotry which sought to make a matron, who became a Roman Catholic, resign her post, and so deprive her of her bread because she had changed her faith. On the other hand, we would condemn the exclusion from hospitals of women whose

form of worship is not so ceremonial as that upheld by the managers. Professor Virchow, the most eminent of German physicians, has recently denounced in the Berlin Municipal Council "the intrusion of religious arrogance into hospital nursing work," and we commend the following sentence to bigots of all sects: "Everybody knows that creeds claim supremacy in the healing of the sick; but we are profoundly interested in keeping away this conflict from the sick-bed, and permitting the spirit of humanity alone to assert itself there."—*The Nursing Record.*

Hypnosis as a Moral Force.—Dr. Berillon, of Paris, proposes to do away with corporal punishment for evil-disposed youngsters and to hypnotize them into sanctity. He has tried it on a number of children addicted to pilfering, lying, self-abuse, pugnacity, possibly cigarette-smoking, and other bad habits, and has succeeded in turning their steps into the straight and narrow path. There have been plenty of children emotionally converted at revival meetings before this, but unfortunately the "suggestion" was, as a rule, short lived in its efficacy.

The Misericordia of Florence is a society of persons banded together to do good. The society has its headquarters, and certain of its members are detailed for service each day. When sickness or accident calls them out, they slip on black or white robes, so that each is undistinguishable from the other, for the essence of their philanthropy is that they ignore all claims to gratitude for their services from those they benefit. Visitors to Florence have often seen these bands stealing through the streets, coming and going from the houses of the sick and dying. Allied to this association, and with somewhat similar objects, is the Medico-Chirurgical Guard, the members of which are young physicians and advanced medical students. They furnish medical aid to the poor, while the Misericordia supplies their other wants.

Cremation in England.—The coming method of disposal of the dead has made less progress perhaps in England than in any other civilized country in the world. According to the last edition of Wilson's "Handbook of Hygiene," there is but one crematorium in all England, namely at Woking, and even after the erection of that one, there was the greatest difficulty in devoting it to its use by reason of the popular prejudice against this mode of disposal of the dead.

The Log of a Ship's Surgeon.—The surgeons on one of the transatlantic lines are required by the rules of the company to furnish the health officer, on arrival, with a detailed description of all cases of sickness that have occurred on board during the voyage. That this is conscientiously done is shown by the following rather quaint report of the medical events during a recent voyage:

"We have inspected all immigrants every day according to the instructions and rules issued by the Health, American, and French officer.

"The Sunday, 24 of July, I have been called by the Steward Daududefin Charles, who was attending his business on the barroom. He was suffering from a violent pain in the hypogastric right part of the abdomen, where he was applying his hands, all the superior part of the body being bended forward. He went immediately to bed, and I could establish the diagnosis of intestinal obstruction. The patient have been a little unwell since three days before, and he was often subject to frequent constipation. I could notice also the coincidence of dark gums with blue line, slow pulse, and contracted abdominal walls. I can omit other symptoms for, no doubt, I was in the presence of intestinal obstruction, probably due to lead colic. The therapeutic treatment of enemas purgatives and prompt relief of pain could not succeed. After two days of constant cares, the second day at night the pulse went very small and frequent, the features pinched with Hippocratic expression. At 10 o'clock, the 25th of July, at night, he has had frequent vomiting of bile and mucus with hiccough, tympanic hypogastric bowels. He died at 4 o'clock in a state of complete exhaustion. He was immersed in the sea the 27th of July, at 3.30 in the morning. The same day, Wednesday 27, Mrs. Louise Deligans, French immigrant, delivered a girl born prematurely of about seven months. The father, French also, was on board with another child. All the family is all right.

"Now I have got in the infirmary Joseph Clolang, an American citizen coming from Switzerland. He has a broncho-pneumonia, and he is in treatment. He felt sick during the voyage. I suspect an interior pathological state of the lungs."

Purifying Water.—Dr. Daremberg, writing in *La Médecine Moderne* concerning the means of rendering a cholera-infected water innocuous, says that this end may be accomplished in one of three ways, viz., by filtering, by boiling, or by the addition of some chemical substance which will destroy the germs of the disease. The first of these methods is, as a rule, ineffective, and can be relied upon only when every detail is most scrupulously attended to. The second is effective, but troublesome, and cannot always be carried out, fire and a suitable vessel for boiling being indispensable. The third method is one which, he says, is equally effective with boiling, and which can be carried out anywhere, and at any time. The purification of water has been effected through the addition of alum, but the author prefers the acidulation of the water, especially in the case of possible cholera infection. Citric acid may be added to the water in the proportion of sixty to eighty centigrammes to the litre. This method is inexpensive, does not impart any unpleasant taste or odor to the water, and can be done anywhere without the need of cumbersome or delicate apparatus. In place of citric acid, tartaric or hydrochloric may be used, if desired.

Ventilation by Means of Heated Walls.—An improved system of ventilation has been introduced in the great hall of the new Sorbonne, in Paris, the principle resorted to being that of maintaining the walls at a higher temperature than that of the air which they enclose. In order to accomplish this, a mixing chamber is located beneath the auditorium, and hot and cold air are mixed to the temperature desired; the air is forced into the auditorium through a great number of small holes in the floor and in front of the seats, the opening being covered by a wire netting. Before the entrance of an audience, the walls are thoroughly warmed by forcing air heated to two hundred degrees into a conduit which delivers the air into a space behind the moulding and close to the floor. The wall is thus heated to a temperature of one hundred degrees—a temperature which, by radiation, will keep the audience comfortable, at the same time ventilating the hall with air at sixty degrees, derived from the mixing chamber. All downward cold drafts are thus prevented, the currents of air all being upward, owing to the heated surface.—*The Sun.*

Trional and Tetronal.—Dr. Ramoni has tried trional and tetronal in fifty-one insane men in the Roman Lunatic Asylum, and in some female patients in the S. Giovanni Hospital. The following are his conclusions: 1. The two new hypnotics are superior to sulphonal and chloral; 2, the patient awakes more easily, and there are no unpleasant after-effects, such as nausea, vomiting, loss of appetite, etc.; 3, the action of the drugs is rapid (thirty to sixty minutes); 4, trional is superior to tetronal, the sleep induced by the former being sounder and more lasting; 5, the sleep (after either of the drugs) lasts on the average six to eight hours, and is not disturbed by dreams.—*Riforma Medica.*

The Consumption of Tobacco is increasing in Great Britain. For the last year it averaged one and six-tenths pound per head of the population. In France it averages nearly two pounds.

DISEASES AMONG INDIANS.

BY A. B. HOLDER, M.D.,

MEMPHIS, TENN.,

ASSISTANT PROFESSOR OF PHYSIOLOGY, MEMPHIS MEDICAL COLLEGE, ETC.; FORMERLY AGENCY PHYSICIAN, CROW RESERVATION, MONTANA.

(Continued from p. 331.)

SURGERY.

Of surgery it may be said the Indian's ideas are few and crude. In his native state, if we except the venereals (and why they were ever included in that branch of medicine in which cures are effected by mechanisms or manual operation, I have wondered), he does not often need the aid of surgery, since accidents are rare. When I inquired of the physician to a tribe of Indians in the Territory (Dr. J. E. Dodson, Osage) concerning surgery among his Indians, he stated the case laconically: "The Osages are very lazy and indolent, and never have any fractures, very seldom any dislocations or wounds." Those that have come infrequently under my care have been dislocations and fractures from gunshot wounds and horses falling. Dislocations seldom receive efficient treatment, and as the hip seems most frequently to have suffered, many Indians are seen who limp from an unreduced luxation of that joint.

The Indian's faculty for retaining one position indefinitely, his inertia, renders the native treatment of fracture quite satisfactory. In fracture of the upper extremities a rude splint is applied, usually at the present day made of part of the tin cans ubiquitous on the prairie; having removed bottom and top and split along the line of solder on the side, it is drawn firmly around the padded arm with leather lace strings passed through holes in the ends of the tin.

In fracture is of the lower extremities, a stationary fracture-box is made by driving parallel lines of short stakes in the ground ten or twelve inches apart and padding this interval into proper shape, usually adopting the double inclined plane as the most comfortable. Frequently the limb, in addition, is surrounded with stout splints or bits of board bound firmly to it, or put up in a kind of wicker work made of willow, described to me by Dr. J. Robinson, of the Western Shoshone Agency.

In a compound fracture of the leg which was treated without my assistance, the fracture-box was filled with cow's dung and the leg encased in this. Whether this as antiseptic surgery or not, I am unable to say, but the result was fairly satisfactory. The clay treatment of fractures, as applied to fractures, and no doubt in use in other tribes, is thus described: [1] According to the latter evidence of Dr. Powell, who has seen abdominal lacerations in men made by the bison, as well as wounds of the head region received under hand-to-hand encounters in war, treated by the Indians, the process is as follows: Plastic clay is selected, such as may in emergency be got from beneath a "buffalo wallow," and made into a thick mud with water; the wound is held together, while a thin coating is applied; then over this is placed a layer of body fibre crossed upon it in every direction; then another coat of mud, and so on, until a cake two inches thick covers the abdomen from flank to flank, the patient being kept upon his back during the treatment. The Pawnees, Utes, Apaches, Sioux, and Comanches make use of silky fibres obtained from plants for holding the clay together. The sage-brush, so common in Indian regions, furnishes one source of supply; another is a species of evergreen, unknown by name to Dr. Powell, which grows high up in the snowy range of the mountains. In extraordinary years, the fall of snow reaches from twenty to forty feet in depth, covering the trees. The snow partially melts, then freezes, and finally sinks in the warm season, stripping down the bark to the roots, and tearing out the inner bark into long thin strips, which are gathered by the Indians for use in dressing wounds. Choice clays are also stored up and kept for the same purpose

Fractures which I have treated myself have united readily, and in about the usual time; trivial wounds, on the contrary, I have found rarely to heal by first intention in this tribe. In a paper read before the Dearborn County, Ind., Medical Society in 1887, Dr. Treon relates the case of a Sioux Indian (Crow Creek Reservation) whose leg was caught by the knife of a reaper and nearly severed at junction of lower and middle thirds, tibia and fibula both badly cut and mangled, and which under conservative treatment healed quickly and kindly. This case is introduced to contrast with my own experience, which has been such that I now seldom unite slight wounds with suture, but leave them open for granulation and suppuration.

Indians take passionately to anæsthesia. Once they have seen it used they desire it for most trivial pains.

An Indian fell from his horse and alighted upon his shoulder, suffering a sub glenoid dislocation of the humerus, and sent for me. When chloroform had been given the mother and other female friends began mourning piteously, crying out that he was dead. Directly the head of the bone slipped into place, and being roused, he related to his friends that he had fallen asleep and had not suffered at all; they were much impressed. When I had cast aside the funnel I had prepared for administering the anæsthetic, I observed them secure and put it carefully away for future use in like emergency.

MISCELLANEOUS DISEASES.

Observations concerning some diseases and other matter not elsewhere found place for are introduced into this chapter.

A Skin Disease I have seen among the Indians differs from any I have seen elsewhere. It is rather a maculation. Occurring on the face about the lips, nose, or forehead, will be one or several solid patches, small or as large as the palm of the hand, resembling cicatrices, especially syphilitic cicatrices, without any pain, itching, or change of sensation, unless, perhaps, slight anæsthesia. The spots are of lighter color than surrounding skin. There seemed no constitutional symptom, and in most of the cases the patches gradually disappeared.

Vitiligo is not rare, and the two most extensive cases I have seen in any race are on this reservation. "Hits on the Hip," two years ago, noticed white spot on belly near navel, thought he ought to change his name to "Spotted Belly" from that. This spot spread and others came, and now he is white save small spots here and there over body of normal Indian color, and the skin of the hands and feet, which are not yet affected. On forearms Indian skin predominates, divided by white spots; the arms are mottled, the color being about equally divided. To-

[1] American Journal of Obstetrics etc., October, 1887.

ward shoulders the skin is white with spots of normal color.

Another Indian, "Child in the Mouth," is in about the same state, but the disease in his case has been of slower growth.

Hysteria.—Several cases of hysteric epilepsy came under my treatment, and milder forms of hysteria are not uncommon; which fact may be of interest to those who consider these diseases the result of higher civilization. Dr. Graham writes me: "Hysteria is very frequent among the younger women. Even those past middle age are subject to it. They have catalepsy and trance. Their hysteria simulates closely many vague and fatal diseases, and it is often difficult of diagnosis."

Chorea.—I saw one case well marked in a Crow girl of good physique and intelligence, about fourteen years of age. *Insanity* in the acute form, I think, is very rare; idiots and imbeciles are frequent. *Epilepsy* is common.

Indians' teeth are nearly always perfect. I have lifted out loose teeth for old Indians at times, but have never had complaint of an aching one. Half-breeds, on the contrary, frequently suffer. I have pulled several for half-breed children in the school, and almost every white person connected with the service has been afflicted with aching teeth, some local condition seeming to hasten dental decay. Earache and otorrhœa are common in both children and adults.

I occasionally see well-marked *arcus senilis* in ancient Indians.

Of *Hare-lip* I have seen two cases, neither with cleft palate, and one case of the latter without the cut in lip.

Indians constantly claim that sores (and especially venereal sores) are from *spider bites*. When closely questioned they admit they never saw the spider and do not remember when it bit them, but are quite sure the sore was thus caused. When there is a swelling as of scrofulous glands about the neck, they say there are *mice in it*, the swelling probably resembling to them the ridge of earth the ground mice make as they run beneath the surface.

Gray Hair.—Bossu, writing in 1771 of the Natchez of Louisiana, says, "the hair of two of the women, very old and infirm, was no more gray than hair of women of fifty-five years in France. The other old woman was one hundred and twenty years of age, and had very little white hair, which is a very uncommon thing among Indians."

Among the Crows I have seen very few white-haired old people, not beyond two or three in the entire tribe, and remarkably few gray-haired. Many of them fifty to sixty years of age have hair jet-black. When it begins turning gray, the custom is to color it with red pigment.

Bald Heads are unknown, even though syphilis with attendant alopecia prevails.

Peculiarities of *hair growth* are to be noted: Its absence on the bodies; its scarcity on the genitals; its scant growth on men's faces; its luxuriant growth on their heads.

Riding astride is the universal custom among Indian women. I have been curious to know if this has any injurious influence on the generative organs. In the few women I have examined I have found *procedentia uteri* rather frequent, but whether due or not to this cause, I cannot say.

Valvular Heart Lesion I have found with unusual frequency among the Indian school-children.

Demonology is recognized as among them. A bright little Indian boy, totally blind, was brought to me. His eyes were large and brown—pretty eyes—and to the observer perfectly normal, but totally without sight. During the early spring of that year he had a fever, and while convalescing became gradually blind. He cannot now distinguish the hand between the eyes and the light; said he could see a little at one side of the right eye, but did not close or avert the eye when sunlight fell directly in it. The pupils contracted and expanded with fair promptness, and in walking the head was held down and to one side as though the habit had been formed because pain existed at one time. The mother explained the spirit (ah-pe-dah-ke) had put something in the eye to put it out, what or why, she did not know.

A Methodist minister named Whitman, missionary at Walla Walla, Oregon, was massacred by the Indians under the belief that he had caused a frightfully fatal epidemic of measles that prevailed among them.[1]

In explanation of a cough the Ute philosophy would tell us that an u nú jûts—a pigmy spirit of evil—had entered the poor man's stomach.[2]

Pain.—The Indian is accounted a stoic. To me the explanation is that in the Indian sensation is less acute. The lesion that would cause torture to a delicately organized woman is not felt by the Indians. "Intellectual development renders us sensible to new pain, and causes us to appreciate as pain what to coarser organism is unfelt."

Intoxicants.

It is the popular impression that every nation possesses some drug or drink that intoxicates. This idea is applied directly to the Indian race by Major John J. Powell, Director of the Bureau of Ethnology, in the first annual report of that Bureau (page 40). He asserts that "every tribe has its potion or vegetable drug by which the ecstatic state is produced." This is undoubtedly true of some tribes; that it is true of the majority I am unconvinced. I can state positively that it is not true of the tribe with which I have been most intimately associated, and I have not the slightest evidence that any Northwest tribe possesses or uses any intoxicant save that furnished them by white men. Among these tribes a state of frenzy or exhaustion has for generations been produced, not, however, by drug or drink, but by fasting and torture. In the state thus produced they dream dreams and see visions from which are drawn inspiration and guidance.

Major Powell elsewhere writes:[3] "In the vicissitudes of savage life, with little or no provision for the future, there are times when the savage resorts to anything at hand as a means of subsistence, and then all plants and all parts of plants, seed, fruit, flowers, leaves, bark—anything in time of extreme want—may be used as food. But experience soon teaches the various effects upon the human system which are produced by the several vegetable substances with which he meets, and thus the effect of narcotics is early discovered, and the savage, in the practice of his religion, often resorts to these narcotics for the purpose of producing an ecstatic state, under which divination may be performed. . . . And civilized man has then an inherited appetite for narcotics, to which the enormous propensity to drunkenness existing in all nations bears witness."

Against the assertion of the distinguished writer, that the savage races under discussion are to share the blame in any considerable degree of this "inherited tendency," it will be seen I have taken issue.

The only intoxicant of which I have been able to obtain reliable information is the tiswin made by Apaches and other tribes of New Mexico and Arizona. It is called by the Apaches tool-pie, which word in sound somewhat resembles the Mexican word pulque, and would point to that source for the knowledge of its manufacture. The method of its manufacture by the Apaches of Arizona is thus described by Captain F. E. Pierce, Agent (1886):

"They manufacture from wheat, barley, or corn, an article called 'tiswin,' which produces intoxication of the worst type when used in large quantities. The grain is buried in the ground until it sprouts, after which it is dried and ground, and then, after boiling a short time with considerable water, is put aside to ferment. The bucks fast two or three days while the tiswin is making,

[1] Century of Dishonor, p. 408.
[2] Report of Bureau of Ethnology, 1879-1880, p. 29.
[3] First Annual Report of Bureau of Ethnology, p. 36.

and in that condition a few cups of it will produce the most frantic intoxication."

Of the Pimas of Arizona the agent states that, "during the months of July and September they gather the fruit of the cactus, and manufacture from it their intoxicating drink, tiswin, when whole villages get drunk."

Special Agent E. E. White, in charge of the Kiowa, Comanche, and Wichita Agency, Indian Territory, 1888, gives the following graphic account of intoxication among the Comanches and Apaches under his charge: "During the past two years many of the Comanches and Apaches, and a few of the Kiowas, have become addicted to the use of a fruit which they procure from Mexico, and which is said by them to be the fruit of a cactus that grows along the Pecos River and the Rio Grande, and on the plains of Mexico and New Mexico. Its common name here among the whites is mescal bean. Its size is about one-fourth of an inch thick and one-half inch in diameter; when dry it is hard and about the color of bright tobacco, and it is not unlike tobacco in taste. The centre of the upper side is covered with a coat of gray fuzz. Its effect on the Indian is believed by medical men to be somewhat like that of bangue. It not only makes physical wrecks of them in a short time, but it destroys the mental faculties as well. While under its effect they are in dreamland, and see the most beautiful visions. One of the beautiful hallucinations which it produces is the belief that everything seen in these visions is real. The Indians have come to look upon this bean—woqui, as the Comanches call it—as an oracle, endowed with the power of revelation."

He then relates the case of a Comanche who, suspecting the fidelity of his wife, determined to consult his woqui to ascertain if his suspicion was true, and for inspiration as to the course he should pursue. That night he ate freely of the woqui. It told him to shoot at his wife three times. If he hit her he would thereby know his suspicion was true. If he missed her she had been faithful, and he should continue to live with her and confide in her. By good fortune or bad marksmanship the shots sped wide, and all was well but for the interference of the civil authorities. The Agent naturally concluded that this hallucination "was liable to assume a dangerous form," and he prohibited the use of the bean. The Comanches at first declared they would rather die than be deprived of their woqui, but afterward were induced gradually to discontinue its use.

Of such an effect from the mescal bean I have not heard from other sources, and, while willing to give full credit to the sincerity of the statement of the gentleman who reports this, I am much inclined to divide part of the effects attributed to the bean between the imagination and the fancy of the *habitué*.

With these few exceptions, it must be said that the intoxicants which work such sad changes in Indian disposition and conduct are among the several such gifts brought to him by the white man's civilization. And when I read reports from every quarter of its damnable effects on the Indian, that "about ninety per cent. of the crimes committed by Indians can be traced to whiskey; that the Indian sober is friendly, patient, kind; that drunk he seems to be animated by a wild desire to cut anybody's throat who intimates he is of less consequence than Napoleon Bonaparte;[1] that it has only its evil effects among Indians, and this ten times multiplied; that there is not an inherent need for a stimulant driving a people if deprived of one to find relief in a worse, I am almost persuaded to become a prohibitionist.

The use of tobacco by chewing was, I believe, unknown among Indians, and is very rarely practised now, only two or three men of the Crow tribe using it in that way.

Smoking has been an Indian custom from time beyond history. The Indian is a luxuriant and habitual smoker. The large consumption in recent years of cigarettes procured from traders is undoubtedly injurious. These are used chiefly by the young men and women of the tribe. To get a correct conception of the Indian custom of smoking it is necessary to understand something of their ideas and method concerning it. The pipe is an emblem. In Indian pictography, carried in the hand, it indicates leadership. To "carry the pipe" is to lead the war party. Smoking is a social and religious ceremony. The pipe has a stem from twenty to forty inches long, the excavation in the bowl is two or three inches deep and not usually over one-quarter of an inch in diameter. Even at the present day, when tobacco is easily obtainable, it is seldom used alone, but is mixed in proportion of one-quarter to one-half with native leaves—in this tribe willow or a species of ground laurel resembling uva ursa. An Indian rarely smokes alone. If a dozen smoke together, socially or in council, usually only one pipe is lighted; this is passed from hand to hand around the circle, each man drawing but two or three whiffs before offering it to his neighbor.

It will be seen that the amount of tobacco consumed by any one Indian, and the amount of nicotine absorbed, even in a day's smoking, is very small indeed—rarely as great, I should fancy, as one strong cigar.

The more serious danger growing out of this custom of "passing the pipe," and one against which I have had frequent occasion to warn white men who join their council or social meeting, is not from the nicotine, but from the possibility of venereal infection, carried by the pipe stem from mucous patches on lips and tongue, so frequent in this tribe that rarely a circle is without one such source of infection.

"Medicine" and "Medicine Man."

There is a good deal of misconception concerning these phrases. The Indian words translated "medicine" and "medicine man" seldom refer to drugs, and in the great majority of cases have no connection with disease.

When the word "medicine" is used, nearly always is meant what Major Powell well describes in the following lines:[1] "Every Indian is provided with his charm or fetich, revealed to him in some awful hour of ecstasy produced by fasting or feasting or drunkenness, and that fetich he carries with him to bring good luck, in love or in combat, in the hunt or on the journey. He carries a fetich suspended from his neck, he ties a fetich to his bow, he buries a fetich under his tent, he places a fetich under his pillow of wild-cat skins; he prays to his fetich, he praises it or chides it; if successful, his fetich receives the glory; if he fails, his fetich is disgraced. These fetiches may be fragments of bone or shell, the tips of the tails of animals, the claws of birds or beasts, perhaps dried hearts of little warblers, shards of beetles, leaves powdered and held in bags, or crystals from the rocks—anything curious may become a fetich."

Such fetich or charm is the Indian "medicine."

The application of the word and idea is still more general. I exhibit to an Indian a photograph of himself I have taken. He exclaims *De mak pash bot sots.* "You are strong medicine," meaning that I am skilled in magic.

"Big Medicine," a Crow Indian, and I were riding together. He endeavored to break the ice of a little stream we were crossing to let our horses drink. Our horses were standing on the ice; he could not break it, but as we turned to ride off, the ice fortunately gave way under my horse's feet. "Big Medicine" said, *D'r-sas ke mak pash*, "your horse is medicine."

The Indians do not say "medicine man," but of such a one among them they say "he is medicine," that is, he is charmed, skilled in magic, possesses supernatural power, inspired in thought and deed. He has little to do with sick people save incidentally, he being priest or saviour rather than doctor. If he chances to cure the ill, it is by his "power," and not through skill in physic.

[1] Robert L. Owen, Agent to Civilized Tribes, Indian Territory, 1876.

[1] First Annual Report of Bureau of Ethnology, p. 41.

He does miracles rather than brew potions. He is a factor for good and evil in Indian life not appreciated at his full merit, but he is not in the province of my work.

Others there are who should better bear the name "medicine men" or women. Some are not old and claim some special power of healing; others are the ancients of the tribe, and, like the old men and women of any race, have from their years of experience accumulated some knowledge of treatment of disease, which knowledge, as again in all races, they are most ready to inflict upon the afflicted.

Even these Indian doctors depend more upon the song and the drum than upon physic. The Indian "medicine man" only evidences that Indian tribes are in that stage of development where priest and physician have not been differentiated, a stage through which our own race passed not many generations ago.

These native doctors are much in the way of the success of the Government physicians, and not by governmental edicts of suppression, but by slow and careful demonstration of the superiority of his methods, is the latter to supplant the former; and this will not be successfully done until the Indian Department not only never removes efficient men from the service, but offers to such inducements sufficient to keep them many years in the service.

I shall lack for words to deny here as positively as I would an erroneous popular notion. It is, that Indians have learned from nature many deep secrets in the use of herbs in curing disease. No more unfounded idea ever prevailed. I could name any one of a dozen sensible country grandmothers who know more of the use of teas and bitters and poultices and roots and barks than an entire tribe of Indians. The long-haired man who shouts from the street corner the virtue of his Indian remedies preys upon this groundless idea. Indians are densely and absurdly ignorant of the properties of the numerous useful herbs that grow on their reservations. A few they do use occasionally internally, more often externally; but not half so many nor so wisely as an experienced negro "mammy."

These statements are made after fair investigation. These were fair because they were begun in the hope of learning something of value; but they were fruitless. They have purges, and in several tribes emetics. I heard of syphilis remedies of pretended virtue, but was unable to verify the story.

Some medicines and medical practices are introduced below.

Tobacco bound to a wound or sore I have seen them use frequently; but whether of their own motion or learned from the whites, I do not know.

As a purge the Indians quite commonly use "alkali;" what the chemical composition of this alkali is I do not know. It pervades everything, soil, air, water in this region, and upon the hills in rocky places "spews" up between the rocks as a clean white powder or solid pieces. It is said to act quite freely upon the bowels, tasting in solution like cooking soda. New arrivals in this country are often troubled with diarrhœa from drinking the alkali water.

Blood letting is a common treatment among the Crows. Frequently one of them comes to me for salve to put on the sore in the bend of the elbow from the knife cut for letting blood. I seldom examine the arm of an old Indian that I do not find one or more scars from former punctures. An Indian whom I was treating for gonorrhœa, becoming impatient, called in an Indian doctor, who bled him from the arm.

Calomel, from my observation, acts with unusual violence among Indians, notwithstanding the fact that I often give them three to five drops of croton oil to secure good evacuation.

A method of Indian treatment of disease, the resulting scars from which I have seen frequently, is to take bits of wood, as, say, the end of a match, a quarter of an inch long. These bits of wood are sharpened and pressed into the flesh close together and in regular lines—I have always found the marks on the anterior forearm—then set on fire and allowed to burn down into the flesh. Often over swellings and about wounds I find numerous parallel and crossing lines drawn with charcoal or some pigment.

A sick Indian *strips;* if male, he keeps on only the breech-clout; if female, a single loose slip—a custom for comfort and cleanliness worthy of imitation. When an Indian is ill, defecation and urination are provided for by digging a hole in the ground near the pallet in the tepee, to be filled in with dirt as used.

The Sweat-house.

This institution is an important factor in Indian life—and death—antedating history and being nearly coextensive with the race.[1]

As in most of the affairs of the Indian's daily life, in the sweat-bath is a puzzling mixing of religion and ceremonial with more material effects, until one is in doubt whether it be natural or supernatural aid that is sought. The ceremonial side I shall leave to those who write of the ethnology of Indian disease and medicine.

The sweat house is the most characteristic object of the Indian country, every camping-place and every permanent abode, river side or mountain top, is decorated with one or a dozen of them. The manner of its use will appear from the following:

A few days ago Shē-gŏg-doo'-chis, our chief of police, came to me for treatment for a vesical inflammation. I gave him medicine I thought best suited, and an hour later called at his tepee to see him.

I found another Indian policeman cleaning off the snow near the tepee and putting up the bent sticks that usually serve as the framework for a sweat-house. I found Shē-gŏg-doo'-chis in his tepee, stripped to the breech clout, kneeling over a pan filled with water, into which had been put some hot rocks. He was thus taking a quickly improvised vapor-bath. I advised that he make his sweat-house inside his lodge, not outside, as he was preparing to do. In an hour I returned and found they had constructed a wick-i-up in one corner of the lodge. It was made just as the outside sweat-houses are made.

Stout, supple poles are stuck in the ground, bent over, and the other ends stuck in, forming a rude half sphere, some three or four feet high, and about as much in diameter at the base. This frame is covered with several thicknesses of blankets, a shallow hole is dug in the ground, a fire is built outside—in this case the usual lodge fire served—and half a dozen or more rocks, weighing four or five pounds each, heated. These are put into the hole in the sweat-house. Four or five Indians had gathered in while the preparations were being made. These stripped and entered the sweat-house two at a time, of the first two, Shē-gŏg-doo'-chis, the sick man, being one. None of the other Indians were at all sick; they were going through the process as a preventive.

The two who went in first took with them a bucket of warm water. They wore their breech-clouts. (They rarely remove this garment even to go bathing). They poured the water over the heated rocks, and the structure was at once filled with hot vapor. Thus shut in air-tight for some five minutes, they whipped their bodies with bunches of horsehair or herbs. At the end of this time the well Indian came out, the sick one remaining and being joined at once by another well Indian, who remained with him five minutes longer, when both came out and were succeeded by the other Indians of the party, including a six-year-old boy.

When the well Indians came out they were wet with vapor and perspiration, and the skin red as a lobster and

[1] Bonneville, writing in 1833, describes them among the Nez Perces and other Northwest Indians. Kirk Monroe (Scribner, March, 1890) finds them still in use among the Florida Seminoles.

smoking like a furnace. They went at once out of the lodge into the snow, and, taking handfuls of it, rubbed themselves vigorously for five minutes. They then returned to the lodge, their bodies still red and smoking, and clothed themselves.

When the sick man came out he lay naked upon his blankets, not going out into the snow; this, however, was in deference to my presence, I having advised against it. Usually, no matter how sick, they plunge out of the sweat-house into the snow, or better, into the river, having broken a hole in the ice.

The next day the sick man was better. I saw all of the other participants, and none of them had any "cold" or other trouble. The temperature was 10° below zero.

Notwithstanding the harmlessness in this case, and the undoubted benefit in some cases, my decided opinion as to their serious effect on Indian health is expressed in another chapter.

GRAPHOSPASMUS.[1]

By R. HARCOURT ANDERSON, M.D.,

ASSISTANT SURGEON TO THE DEMILT DISPENSARY, NEW YORK, AND DISTRICT PHYSICIAN TO THE NEW YORK LYING-IN ASYLUM.

GRAPHOSPASMUS, from grapho—I write—and spasm, denotes, according to Reynolds, a chronic disease characterized by the occurrence of spasms when attempt is made to execute a special and complicated movement, the result of previous education, such spasm not following muscular action of the affected parts when special movement is not required.

The term graphospasmus is faulty, inasmuch as it does not signify the exact abnormal condition which involves inco-ordination more than it does spasm.

Benedict calls this and analogous affections the professional neuroses of co-ordination; or, as Duchenne has it, there is an impotence in respect to the particular position and movements involved in writing, or any movement the result of previous education; there is no lack of ideas, no disease of intellect, and the motorial apparatus is intact except as regards the particular movement or movements.

We have three different forms of the affection, viz.: 1st, a spastic; 2d, a paralytic; 3d, a tremulous form—the paralytic form being often associated with sensation of pain—the difference in the varieties being rather of degree than of kind.

As a rule, the part affected is the hand, although in a few cases the foot was the seat, and in one instance in a professional clarionet-player, the tongue was affected. Where the hand is affected a curious feature is a change in the nutrition of the nails, which points, of course, to nervous agency.

In a typical case the clinical history is about as follows: A period of overexertion of the hand, coupled usually with anxiety of mind, the muscles become fatigued, the writing changes in character and becomes irregular; finally the muscles refuse to do their work, they do not co-ordinate in movement, and other muscles are called into action.

Normally, in writing, the supervision of the higher centres cease and writing becomes automatic, but when the above disability occurs the attention must again be directed to the act. Usually the growth of the affection is slow, but may be sudden, as after prolonged exertion. As the literature on the subject is very scant, there is no reliable means of estimating the frequency of the affection; but judging from the number of instruments and machines in use which require educated movements there is reason to believe it more frequent than is generally supposed.

It is very desirable that we recognize the importance of this affection as a precursor or forerunner of more serious diseases either of the nervous or other systems; nearly all authors agree on this point, and here again we lack statistics or information as to the number of cases in which other disease followed, the affection being an evidence of depressed vitality; as a rule, the number is probably large.

Regarding etiology, our knowledge on the subject is largely theoretical; the numerous theories may be divided into, 1, centric, and 2, peripheral or myopathic. I will briefly mention a few of the most plausible. Duchenne rather vaguely states that the cause is central, but that there must be a predisposition, and says that when the unaffected hand is called into action it often becomes affected, which proves nothing. The late Mr. Solly, of England, advanced the theory that the cause was granular disintegration of the cervical portion of the spinal cord; another, that there is loss of irritability of muscle, and that the use for purposes other than writing is more apparent than real; Burdon-Sanderson, that the lesion is situated in the corpus striatum; while Dr. G. M. Poore, of England, holds the cause to be peripheral, and states that muscles which are trained to work together fail when one of them no longer does so. Bartholow also advocates the peripheral theory.

The Solly theory, if I may be permitted to call it so, that the cause is granular disintegration of the cervical portion of the spinal cord, that is, the posterior white columns, which include the columns of Gall and Burdach, is objectionable because—1, The disease sometimes comes on suddenly, whereas granular disintegration of the spinal cord would necessarily take more or less time; 2, change in the cord would be likely to produce more pronounced constitutional effects than we get in graphospasmus; 3, if taken in time, rest will cure a good many of the cases, but it is hardly reasonable to suppose that rest will restore the cord if granular disintegration has taken place.

The theory that there is loss of irritability of the muscles has no basis; it is simply built on sand, out of very poor material, as it is very evident to anyone investigating the subject that the difficulty in co-ordination lies only in executing the particular movement or movements, and that muscular action in other respects is normal.

Irritation or injury of the corpora striata is followed by general rolling or turning movements, and they may in some way be connected with co-ordinate movements of the hand; but they are principally interesting from the fact that Willis thought the soul of man resided therein. The myopathic theory, if we take this as meaning disability of the muscle proper, it is not fact; as stated before, they act normally except as regards the particular movement; or if we take it as meaning that the cause is situated in the peripheral distribution of nerves, it will not bear careful investigation.

It is agreed by all physiologists of any standing that the great co-ordinating centre is the cerebellum, the white columns of the spinal cord being also involved principally as conductors. I now put forward the theory that we have in the cerebellum distinct focal centres of co-ordination similar to the motor focal centres in the cerebrum, and likely subordinate to the same. If this is fact, irritation or disease of such a centre, presiding over co-ordination of the hand, would produce muscular action similar to what we get in graphospasmus.

It has been shown that extirpation of the middle lobe of the cerebellum is always attended with inco-ordination; but when parts other than the middle lobe are injured it is possible for co-ordinate movements to take place after the primary effect has passed away, proving, in a sense, that the middle lobe has more to do with co ordination than other parts.

Unless I am mistaken, there is not a single case on record where the patient was followed up and an autopsy made; it may seem a very trivial matter to make an autopsy for, but will not the knowledge of the exact causation of this affection give us, to some extent, knowledge of some of the neuroses, the causation of which, at present, is obscure, and will it not be very useful to the physiologists? If we are asked, for instance, at the present day, the etiology of paralysis agitans, we would have

[1] Read before the New York County Medical Association.

to plead ignorance; we do not even know whether it is situated in the cord or brain.

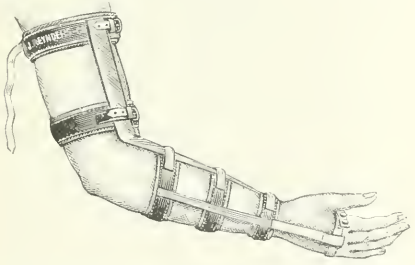
Regarding diagnosis, there is no difficulty in recognizing the affection, though it might possibly be confounded with multiple sclerosis, beginning muscular atrophy, or agraphia. The polymorphous character of multiple sclerosis renders it peculiarly liable.

The prognosis in regard to cases which become chronic is not good. A large percentage never recover the normal use of the hand, and some patients, therefore, have to change their occupation.

In treating, we may try the following: In the acute form, rest will cure a good many cases.

Bardsley, of Manchester, England, recommends sleeping on an inclined plane, the head of the bed being twelve inches higher than the foot; this method is not very successful. Nussbaum has lately invented a kind of bracelet to which the penholder is attached, to be worn during writing, which is effective in acute cases.

Referring to electricity, faradism undoubtedly does harm; galvanism only should be used; avoid all strong currents, apply the stabile anode to the brachial plexus and to the different nerves and muscles for five minutes at a time, place cathode in the vicinity of cervical vertebræ. Pain should be treated specially; hypodermics of strychnia or atropia injected into the muscles will be of benefit.



Two methods of treatment remain to be mentioned, both of which, I think, are original.

First, I will briefly mention a surgical operation by which we can divide some of the flexors of the carpus and get union between the belly of one muscle and the extremity or tendon of another. Of course this will distort the anatomical relations, but it will have a tendency to prevent the inco-ordination, and is not very intricate; and second, the apparatus which I present to-night.

Four months ago a patient came to me with the following history: About seven years previous, after working very hard at his business, which was that of dry goods, he became sensible of fatigue, and later movements of the right hand became inco-ordinate. I must here state that the method of folding some kinds of dry goods call into play a certain set of muscles in a certain way. On examination I found that a spasm of the flexors of the carpus took place on voluntary motion, there being also a weakened condition of the flexors of the forearm.

As the patient had been under the care of some eminent neurologists, and had for a long time been taking a liberal supply of drugs, faradism, etc., I came to the conclusion that only something mechanical would help, and remembering that when a student I had studied the muscles of mastication by means of a skull and small pieces of rubber, after some deliberation I devised the following apparatus: Five bands of soft leather were made to buckle on the limb, two on the arm, and three on the forearm, the upper band being situated about the insertion of the deltoid muscle and prevented from slipping by means of a small strap attached to a shoulder-brace; the lower one at the wrist. A strong piece of rubber about two inches wide was attached to the upper band, and passing through loops on the intermediate bands, was inserted into the band at the wrist in such a manner that when the forearm was flexed the rubber was lax, but when extended, was put on the stretch. To overcome the spasm of the flexors of the carpus, a small band of calfskin was passed around the hand, just behind the knuckles, and secured on the palm by a clasp; to this carpal piece, on its dorsal surface, was attached, at right angles, a small strap of calfskin, which was continuous with a piece of rubber, which in turn was sewed to the leather band just below the elbow, in such a manner that when the carpus was extended to its fullest extent the rubber was lax, but when flexed, even to a small extent, the rubber was drawn taut or stretched, thereby overcoming the spasm.

At first, instead of the leather bands I used two paper splints, after the manner of Dr. J. Marshall Hawkes, of this city, one on the arm and the other on the forearm. With modifications the mechanism is applicable in a large number of cases of paralysis and allied affections, notably to the lower extremities in locomotor ataxia; it is not cumbersome or bulky, can be worn over the sleeve of any ordinary shirt, and is not conspicuous, only the carpal pieces showing below the coat-sleeve.

Coupled with tonic treatment and galvanism it has improved the condition of the patient by giving confidence in executing movement and controlling inco-ordination to a certain extent.

The apparatus was made by Reynders & Co., of New York.

221 West Twenty first Street.

NOTES ON TWO CASES OF SPONTANEOUS INTERMITTENT HEMORRHAGES.[1]

By A. BROTHERS, B.S., M.D.,

PHYSICIAN TO THE OUT-DOOR BUREAU OF RELIEF OF BELLEVUE HOSPITAL.

Case I.—Lizzie K——, aged nineteen, single, under observation since the latter part of 1887. Her family history is negative. Parents are both alive and well. No bleeders remembered in grandparents or parents. One brother and two sisters are enjoying good health, and are not prone to hemorrhages. In the patient's personal history the first illness experienced was measles, at the age of two. At nine she went through an attack of scarlet fever and diphtheria. Shortly afterward she suffered from pain and swelling in the lower limbs. At eleven she was first troubled with dyspnœa. At twelve, the symptoms on which the chief interest in her case centres, namely, the spitting of blood, began. This came on imperceptibly without any special illness or traumatism to mark its advent. Ever since their first appearance, seven years ago, these hæmoptyses have, with certain periods of relief, been almost of daily occurrence. For long periods at a time she has averaged six to twenty a week. She has each year, for three years past, enjoyed immunity for several weeks at a time, while spending the summer at Lancaster, Pa. The quantity of blood brought out at a time is never very great, never more than a teaspoonful. It is bright red in color, aërated, usually fluid, but sometimes comes up in small clots. It is neither coughed up nor vomited. There is simply a slight gagging sensation, followed by the hawking up of the blood. In 1890 she first became unwell. After remaining absent for about six months, the period again came on, and recurred regularly each month up to six months ago. Since then she has suffered from metrorrhagia. The menstrual flow returns every two weeks, and lasts a week, during which five or six napkins are saturated daily. During several weeks in 1889 she suffered from persistent bleeding from the right nostril. Beyond these hemorrhages she has never suffered from unusual bleedings after traumatisms, or otherwise. Among other symptoms which have disturbed her, pain in the left side has occupied a prominent place. Although never confined to bed with polyarthritis, she has frequently suffered

[1] Read at a meeting of the Associate Alumni of Bellevue Hospital, April 6, 1892.

pain, occasionally with swelling in the fingers, wrists, elbows, and knees. As long as she has been under my observation she has been subject to headaches, dyspnœa, and palpitation. Although her temperature has always been normal, her pulse has always beat too rapidly. Five years ago her pulse-rate ranged between 120 and 130; at present it counts 80 to 100. It has always been of good volume and regular. In June, 1889, she began to suffer from "fainting spells." Without any premonition she would suddenly lose consciousness and fall. These attacks recurred a number of times, daily or weekly, and on one or more occasions happened while on the street. For the past six months she has been free from these attacks. For a period of six weeks, recently, she suffered from a continuous pain in the right temple, severe enough to interfere with her nightly rest. This has now left. In spite of all these disturbances her general health did not for a long time suffer. Her appetite, complexion, and strength were good. Although of small stature—her mother is also a small woman—her form is well-rounded, and shows a fair amount of adipose tissue. Within the past year the continuous drain from the hæmoptyses and metrorrhagia have begun to tell on her. At times she has been quite anæmic, the healthy color of her cheeks has turned sallow, and her lips have become whitish. Her appetite lately has been quite poor at times.

In regard to the results of physical examination there is little to be said. Four years ago Professor A. Jacobi examined the girl and thought he found slight consolidation of the right apex and a faint mitral systolic murmur. He has been kind enough to examine the girl again a few months ago, and writes that he no longer finds the mur mur and believes the consolidation has melted away. Therefore we cannot attribute the hæmoptyses to either cardiac or pulmonary disease, for, surely, after five years, during which time the patient has been continuously under our observation, some signs at least of a progressive disease of heart or lungs would have manifested themselves. Nor is there any evidence of disease of the pharynx or larynx to be found. Repeated local examinations by Dr. Allen, laryngologist to the Out-door Bureau of Relief of Bellevue Hospital, have failed to locate the source of bleeding in the upper air-passages. Hence we are driven to the conclusion that our patient is suffering from a disease of the blood-vessels—general incompetency or hyaline degeneration (according to Professor Jacobi)—which has restricted itself to a certain set of blood-vessels, leaving the vascular system elsewhere apparently intact. It is possible that the metrorrhagia is to be explained in the same manner, for a local examination has failed to discover any other cause.

In the treatment of this case all of the hæmostatic drugs known to medical science have been used without avail. The only measures which have afforded temporary relief have been either complete rest in bed for weeks at a time, or complete change of surroundings by a visit to the country, which has only been possible during the summer months. At present she is under a prolonged course of treatment with arsenic as a tissue-builder, and ergot to keep her blood-vessels well contracted.

In concluding the history of this interesting case allow me to recapitulate the following facts: 1. Absence of a family history of hæmophilia. 2. Occurrence of joint symptoms from an early period. 3. Hæmoptyses for the past seven years. 4. Complete absence of physical signs pointing to disease of the heart, lungs, or other organs. 5. Metrorrhagia of a severe type. 6. Epistaxis, at one time lasting many weeks. 7. Rapid heart-action. 8. "Fainting spells." 9. Slow impression on the general constitution.

Case II.—Mr. B——, aged forty-five, native of Russia; married, father of five healthy children. Family history is negative. His father died suddenly of heart failure at the age of seventy. His mother is still alive, having again married and given birth to a number of other children, all of whom are said to be healthy. Excepting a tendency to readily bleed from the gums, our patient does not remember any severe hemorrhages during early childhood. No other members of his family have been subject to hemorrhages. At the age of twelve months he is said to have suffered from a severe attack of inflammation of the brain. To the excessive administration of calomel during the course of this disease was attributed an extensive destruction of the palate, which, for many years, interfered with speech and deglutition, and which has left a distinct nasal twang to his speech to day. At the age of fifteen years he was taken to Königsberg, where he underwent two plastic operations at the hands of Wagner and Bure, as a result of which his palate is now almost perfectly intact. During the operations no anæsthetic was used, and he claims that he lost a very large quantity of blood. At the age of twenty-four he remembers being very much troubled for a period of four or five months with bleeding gums. The following year was a critical one in his life. Without premonition he one day suddenly began to bring up large quantities of bright red blood through the mouth and nostrils. Being in affluent circumstances he consulted no less than seven of the most eminent physicians on the Continent, including Professors Traube and Skoda. Five of them located a lesion in one lung, but two failed to find any pulmonary trouble. He was ordered to various watering-places and followed a quiet life. For a period of eighteen years all went well. He got married and had five children. Three years ago a series of reverses, due to governmental persecutions, began, and from being a very wealthy man he suddenly became quite destitute, and decided to leave his native soil. In May, 1889, he consulted Professor Nothnagel, of Vienna, as to any possible danger in the change. He pronounced him, after careful examination of heart and lungs, perfectly sound. Shortly afterward, at Paris, he noticed he was passing fæces of a black and tarry nature. He consulted a physician, who, without examining the passages, decided they were due to an iron tonic he was taking. He then crossed to this country, where he began the first genuine work of his life as a pedler. A year ago he noticed he was again passing this same black, tarry matter in his stools. This kept on for several days, when suddenly he was taken with hæmatemesis, during which he vomited nearly a basinful of blood, after which he passed into collapse. I saw him now for the first time, and requested Dr. A. Jacobi to examine him in consultation. He confirmed the existence of an apparently healed-up, ancient, consolidation of the right upper apex. We were sure, however, that the blood came from the stomach, and, although there was complete absence of local pain or gastric symptoms, we inferred the existence of an ulcer of the stomach. It may be here parenthetically remarked that he completely denied ever having suffered from any gastric symptoms whatsoever. Under ice locally, and morphine and ergot internally, the hemorrhage was soon under control. After a few weeks in bed he was allowed to get up, particularly as there was no further trace of blood by stomach or bowels. He remained perfectly well for six months, being able to attend to his business without interruption. Then, without any assignable cause, he again noticed, for several days, the tarry black passages, which were, as before, followed by the vomiting of large quantities of blood. He rapidly passed into a condition of profound collapse, and we despaired of his life. The same treatment was resorted to, and with good result, for in a very few days the vomiting ceased and the blood disappeared from the passages. The gums, however, were quite spongy and bled very readily. This time he remained in bed for nearly two months. I ordered him to lead a very quiet life, to be very careful of his eating, and not to resume his work.

In spite of these precautions, toward the middle of January of the present year—after having spent four months in good health—he again noticed the peculiar black and tarry passages. I at once ordered him to bed,

with ice to the stomach, and the same internal treatment as before. Despite our care he passed into a condition of marked collapse; he became intensely cold and anæmic, the pulse became small, ranging between 120 and 130 per minute, and, although no sign of blood was visible externally, there was no doubt of internal hemorrhage. A continuous gagging sensation was kept in check by cracked ice, and the bowels were kept costive. After a week he was rallying nicely, when, to relieve the constipation, an enema was ordered. He passed a large-formed movement of jet black color, followed by a little free blood, and then went into the worst condition of collapse he had yet experienced. The surface and extremities became cold, the face assumed a ghastly hue, the voice became reduced to the faintest whisper, and the pulse was too small and rapid to be accurately counted. With this tenesmus came on, accompanied by the passage of dark red fluid blood in small quantities. There was no doubt of fresh internal hemorrhage. Under ice, morphine, lead, and digitalis, freely given during three days, he gradually emerged from his dangerous condition. At the time of the last hemorrhage he complained of a pain, with stiffness, in the right intermaxillary articulation, and for a number of weeks he could hardly separate the jaws. This symptom is now entirely well. For a time he ran a low fever of 100° to 102° F. (axillary). At no time has he suffered from epistaxis, hæmaturia, or petechiæ. Careful and repeated examinations by Dr. Jacobi and myself failed to reveal any growth in the abdominal cavity, or any gross lesion to which the gastro-intestinal hemorrhages could be attributed, and, in view of the history of former hemorrhages, dating as far back as twenty years, we came to the conclusion that the patient was suffering from disease of the blood-vessels in the region of the stomach and duodenum. Within the past four weeks a hard tumor, the size of a hen's egg, has become evident in the epigastrium. This is situated rather to the left, moves most with inspiration, and is apparently connected either with the stomach or the left lobe of the liver. It is probably carcinomatous. The patient is still very weak, very anæmic, and much emaciated. He is under treatment with methylene blue, but thus far he has rallied much more slowly than from the former attacks.

In reviewing the history of this case I would draw attention briefly to these facts: 1, Absence of family history of bleeding; 2, early appearance of bleeding of the gums which has recurred from time to time; 3, pulmonary (?) hemorrhages twenty years ago; 4, complete immunity for eighteen years; 5, probable passage of blood in the fæces three years ago; 6, three attacks of gastro-intestinal hemorrhage during the past year, separated by months of apparently perfect health; 7, arthritis of the intermaxillary joint; 8, insidious development of carcinomatous (?) growth; 9, the possible connection between the condition of the blood-vessels generally and the tendency to carcinoma.[1]

A few remarks on hemorrhage may not be out of place. In general, hemorrhages are either traumatic or spontaneous. With the former we are not concerned at present. The latter variety may depend on lesions which are demonstrable or not. Tuberculosis, carcinoma, simple ulcers of the gastro-intestinal tract, may be mentioned as the most frequent causes of spontaneous hemorrhage, due to distinct lesions, which can be readily seen. Among the less easily demonstrable causes of spontaneous hemorrhages are those due to disease of the blood-vessels themselves. Predisposing causes in such cases have been attributed to anæmia of infancy, congenital syphilis, hæmophilic diathesis, arthritic diathesis, cold and fatigue, malaria,[2] with its tendency to induce hæmaturia, indulgence in certain articles of food, such as asparagus[1] and rhubarb,[2] have all been accused of predisposing or exciting hemorrhages.

In the first case presented to-night I believe the cause of the hemorrhage to lie in the condition of the blood-vessels—some change not visible to the naked eye. In the second case the intra-abdominal growth may account for the hemorrhages of recent date, but would the man have lived so long and with so few symptoms if this tumor were the cause of the hemorrhages occurring over a year ago? In regard to the hemorrhages of twenty years ago, we are justified in assuming that they were due to a pulmonary lesion at that time. But, with the tendency to bleeding from the gums, are we not justified in suspecting an underlying disease of the general vascular system?

The two cases are somewhat suggestive of hæmophilia. Although the pathology of this disease is not positively determined, it is fairly assumed to be due to three causes: 1, Deficiency in the quality of the blood; 2, deficiency in the structure of the walls of the blood vessels; 3, a possible excess in the entire volume of the blood. The cases resemble hæmophilia in the ease with which the hemorrhages are repeated and in the presence of arthritic symptoms. The difference lies in the absence of a family history—hæmophilia being the most hereditary of diseases—and in the absence of a tendency to violent hemorrhages after traumatisms. The case of the girl very closely resembles one lately reported by Sir Andrew Clark,[3] and attributed to the arthritic diathesis, in which there were recurrent hæmoptyses, without any lesion to account for them, *i.e.*, no coarse anatomical lesion of heart or lungs was demonstrable.

In early childhood the changes which may occur in the blood-vessels are of two varieties: 1, Congenital incompetency or thinness of the walls; 2, disease or alteration of those walls. According to A. Jacobi,[4] "there are blood-vessels so thin and incompletely developed, and integuments so poorly formed that bleeding will now and then make its appearance spontaneously." He refers to the case of a baby, in which the blood would trickle from the surface of the lower extremities like perspiration, in drops, day after day, until the baby died. Trousseau and Virchow alluded years ago to such congenital thinness of the blood-vessels as a cause of hemorrhage and chlorosis. Nor is this condition rare, for in all children the blood-vessels are naturally thin, and it is the exaggerated thinness which becomes pathological. Such cases have been examined post mortem and described by Klebs, Weber, Cruveilhier, Voigtel, and Dieulafoy. Hereditary syphilis may produce a hemorrhagic diathesis by defective general tissue-formation. Congenital atheromatous degeneration of the blood-vessels is quite rare, but has been known to occur. Cases of this nature have been reported by Montard, Martin, Sanné, and Jacobi. As a result of the anæmia of childhood, blood-vessels may become thin and undergo fatty degeneration (Ponfick). Lastly, another form of degeneration of the walls of the blood-vessels is that described by P. Meyer as "hyaline" degeneration. To this variety of vascular disease Hoffmung attributes a case of aneurism in a branch of the pulmonary artery in a baby of ten months, which died of hæmoptysis.

The two patients presented to-night are specimens of some of the difficult cases we are apt to meet with in practice. They prove the wisdom of never jumping to a conclusion in a hurry. They suggest the necessity in all doubtful cases of patiently waiting and watching till time clears the mist which surrounds the true state of affairs.

162 Madison Street.

[1] Since writing the above the patient began to waste away, and finally died of exhaustion. No autopsy was permitted.

[2] See case of hæmophilia, attributed to malaria, by Koch, British Medical Journal, 1890, vol. i., 1301.

[1] Reginald Harrison mentions a case of profuse hemorrhage of the bladder after excessive indulgence in asparagus, Medical Annual, 1891, p. 238.

[2] E. H. Fenwick (ibid.) regards rhubarb as a sufficient cause to produce the same result. [3] See Medical Annual, 1891.

[4] Most of the material of this paragraph is taken from two excellent monographs by A. Jacobi, on Extra-Cranial Aneurism in Early Life (Verhand. des X. international medicin. Congress, Berlin, 1891), and Heart and Blood-vessels in the Young (Brooklyn Medical Journal, March, 1888).

Clinical Department.

THE TREATMENT OF CHOLERA.

By EDMUND CHARLES WENDT, M.D.,

NEW YORK.

(Concluded from p. 339.)

The Treatment of Well-marked Cholera. — Although we have repeatedly expressed ourselves to the effect that we have practically no power to always arrest a fully-developed attack of Asiatic cholera, nevertheless the principles which should guide the physician's recommendations and actions seem to us to be plain and unequivocal. The enforcement or even encouragement of any rigid theoretical plan of dealing with the unfortunate subjects of a pronounced attack seems utterly reprehensible.

As in other diseases, so too in cholera, the most reliable indications for medical interference are furnished by a knowledge of the disease-processes underlying the symptoms observed by the physician. Accordingly, if it becomes evident that the normal absorbent functions of the gastro-intestinal surfaces are completely reversed, it is worse than useless to introduce large quantities of powerful drugs and stimulants either from above, or (as has been quite recently often done) from below. We say worse than useless, for the reason that the uncertainty in duration of the different stages of cholera makes it possible for reaction to occur with enough medicine or alcohol, or both, in the alimentary canal to kill the weakened patient, by suddenly acting upon his system immediately after the rapid revival of absorption. There is not the slightest doubt that sudden death, so frequently observed shortly after apparent reaction, has been due in some instances to such causes. The oral administration of drugs is, therefore, only indicated while intestinal absorption continues. Again, the subcutaneous connective tissue so quickly shrinks during collapse that its power of absorbing is largely reduced or completely suspended.[1] Nevertheless, whenever potent remedies are demanded, hypodermic injection offers a better chance of effective medication than the swallowing of mixtures, pills, or powders, and also than the much vaunted enteroclysis of Cantani and other recent Italian writers.

Knowing, then, that the internal use of drugs during collapse is of no avail, it seems unnecessary to enumerate the countless host of remedies that have been and continue to be recommended by writers of all nationalities.

Before the occurrence of collapse, and during the stage of profuse discharges, it is generally advisable to administer small doses of morphine hypodermically. This may at least to some extent quiet the patient and diminish his sufferings. But the drug should never be "pushed," as, for example, is commonly done in peritonitis. For the relief of persistent thirst small quantities of iced fluids, such as plain water, carbonic acid water, and especially water weakly acidulated with mineral acids or freshly expressed lemon-juice, and similar drinks, may be frequently given. Little bits of ice taken every few minutes are also allowable.

Some writers have insisted on completely withholding these harmless and grateful beverages, believing that they increased vomiting and favored the intestinal flux. But there is not the slightest foundation for entertaining such an opinion. Indeed, it would be downright cruelty to refuse the momentary relief that cool drinks often give the patient. It is only too true that thirst is not quenched thereby, and that the stomach may immediately reject the eagerly swallowed liquid.

Yet, in some cases the relief is so apparent that we have no hesitation in affirming it to be the physician's duty to see that drinks are not withheld. In well-marked collapse it is best to stop all medication. Moreover, in this condition heat applied to the body, frictions, embrocations, and similar well-known measures, have no power to call back to the surface the fast-ebbing tide of warmth. But before that time such measures may be employed to advantage. Semmola has strongly urged the warm bath, repeated every two or three hours, as a possible preventive of collapse. Yet this must often be fatiguing and injurious. He admits, also, that to bathe a patient during collapse would have no more effect than to deal similarly with a corpse. But on the other hand, he insists that the warm bath has a calmative effect, and a rallying influence, especially noticeable in the stage of premonitory diarrhœa.

Dr. J. C. Peters has used pieces of unslaked lime, wrapped in wet cloths and put in bowls under the bedclothes, successfully in incipient collapse. The heat produced is very great and grateful, and there may possibly be some disinfecting power in this process. A pack in blankets wrung out in hot cayenne or mustard water is useful; and it is very easy, when the blankets cool or dry off, to pour very hot water upon them without removing them or disturbing the patient. Slaking lime used in the way just mentioned is easy of application, and does not tire or weaken or disturb the patient.

An energetic doctor once gave his collapse patients a hot bath, made them drink all the hot water their stomachs would hold, and then pumped not only their bowels but their bladder full of hot water, and complacently said if anyone could do more to warm a patient up he would like to hear of it. We can only add, slaking lime in bed (Peters).

Semmola directs that the temperature of the water used for the baths should not fall below 100° F., nor much exceed 104° F. If the muscular cramps prove rebellious to gentle frictions with warm flannels or slightly stimulating or anodyne liniments, if they remain uninfluenced by a hypodermic injection of morphine, the physician may allow the inhalation of chloroform carried to the point of partial anæsthesia. This may be repeated from time to time without fear of disastrous effects on the heart. But unless thoroughly reliable and competent trained nurses be in waiting, the attending or some other physician must personally direct its administration.

Dr. Maclean[1] says that "cramps are best relieved by the use of chloroform, given in doses of five or six minims in a little water, and if vomiting be excessive a little may be sprinkled on a pad of lint covered with oiled silk or gutta-percha tissue, and applied to the epigastrium; or spongio-piline may be used for the purpose. I have used chloroform in this way both externally and internally, very freely, and always with good effect."

Dr. Macnamara speaks strongly in favor of chloroform. Having pointed out the great importance to the patient of procuring rest, he says: "In furtherance of this latter object, I know of no remedy more efficacious than chloroform. If the patient is in much pain and very restless, I strongly advise his being placed under the influence of this anæsthetic. The chloroform must be administered by inhalation, and its full effects may be safely induced; or at any rate, we may put the patient into a sound and comfortable sleep. . . . We must be prepared to continue the action of the chloroform, perhaps for four or five hours, or even longer, according to circumstances."

Dr. Parrot[2] also favors the employment of chloroform in cholera. He used one to two drachms of chloroform daily in severe cases, and less in mild ones. The vehicle was water one hundred grammes, and syrup of quinine twenty grammes. This mixture was given in tea, a tablespoonful every half-hour; at the same time iced beef-tea was given very frequently in small quantities. Warmth was applied to the skin, and dry and stimulating frictions were used. Chloroform given in this way calmed the

[1] Still subcutaneous injections of weak acid water, or even of salt and water, have at times appeared to stem the tide of outflow from the bowels, as tonics and astringents acting from behind.

[1] Lectures on the Treatment of Cholera, by Deputy Inspector-General Maclean, M.D., Professor of Military Medicine, London Lancet, February 3 and 17, 1866.

[2] Gazette hebdomadaire, December 8, 1865.

anxiety and epigastric pain, and seemed to diminish the frequency of the vomitings, which were also less painful.

Dr. Hartshorne,[1] in 1854, spoke as follows concerning the use of chloroform: "Experience has shown that, taken into the stomach, it is as totally free from danger as any other drug; and its employment is destined to be yet much more widely extended; a fluid-drachm of chloroform taken by the stomach is not more than equal, in soporific effect, to thirty or thirty-five drops of laudanum. In doses of fifty to seventy-five drops (about fifteen minims), I have given it every half-hour for several hours together. It differs from the opiate preparations in the promptness of its hypnotic action, the much shorter period of its duration, a less degree of cerebral oppression, and the absence of all stimulus to the circulation. It might be called a "diffusible narcotic," comparing in this respect with opium as ammonia does with alcohol. To produce much effect with it, repeated doses at short intervals will be necessary. Its pungent property causes it to require plentiful dilution, which is of course facilitated by the action of some demulcent. Perhaps the orgeat syrup is the best. Every fluid-drachm of chloroform should have at least two fluid-ounces of water with it when taken; and it will need, if in ordinary gum mucilage, considerable agitation to re-suspend the particles immediately before swallowing. When taken in aqueous mixture alone, however, unless in very small doses, it produces nausea with some persons. This is entirely prevented by the addition of a strong aromatic, or still better by giving the chloroform in aromatic tincture. From the ready solution and kindred action of camphor with chloroform, their combination has become a very common one. For many purposes, however, a still better preparation is a sort of chloroform paregoric, or compound tincture of chloroform, *e.g.*: ℞. Chloroform, f ʒ ij.; sp. camph. et tinct. opii, āā f ʒ jss.; ol. cinnamon, gtt. viij.; alcohol, f ʒ iij. M. et fiat tinctura. Dose, from five to thirty minims, or more, as required. The most admirable effects have been witnessed from the administration of chloroform, as above combined, in malignant cholera.

Recently Dr. M. Desprez[2] has also advocated the employment, both externally and internally, of chloroform. He believes that by this means from eighty to ninety out of every hundred persons in the algid stage of cholera could be saved. He bases this extravagantly hopeful view on his own experience, and on that of other physicians in Asia Minor, India, and Cochin China. The following is his formula:

Chloroform	1 gram (15 minims)
Alcohol	8 grams (2 drachms)
Acetate of ammonia	10 grams (2½ drachms)
Syrup of hydrochlorate of morphia	40 grams (1¼ ounce)
Water	110 grams (3½ ounces)

Dose: A tablepoonful every half-hour.

Without sharing Desprez's sanguine views, we nevertheless have reason to believe that chloroform may often be used with advantage, especially for purposes of inhalation. But ether is objectionable, and nitrite of amyl, either inhaled or injected beneath the skin, has not realized the expectations that were formed concerning it.

Another common symptom that may become so distressing as to require the inhalation of chloroform, is singultus. But before having recourse to this means, the hypodermic use of morphine, an epigastric sinapism, a spice poultice, or a blister should be tried to stop the hiccough. Where there is reason to believe that a limited amount of absorption still takes place in the alimentary canal, various stimulants may be administered in a tentative way, in order to secure the prevention of collapse. Alcoholic beverages, such as Burgundy, Tokay wine, port wine, brandy and water, or champagne, may then be given. In the same way, if indicated by the condition of the patient, various excitants, such as the ammoniacal preparations, camphor, and musk, may be employed. But, as previously pointed out, if collapse comes on in spite of their moderate exhibition, they should be at once discontinued. Even then an attempt to stimulate cardiac action by the hypodermic use of similar medicaments, including brandy and ether, may be made. But this too must not be persisted in.

Obviously, it is impossible to lay down fixed rules for the guidance of the practitioner in this direction. But, as already stated, the general principles governing intelligent action are by no means as obscure as might be supposed from the confused and conflicting statements of many authors.

The writer may be permitted to say here that he strongly deprecates the blind tapping about among various supposed remedies, in the vain hope that a lucky accident may result in the discovery of a really curative agent. The physician should make every honest effort to stay the march of the disease by employing those means the action of which he is familiar with. But to use the living bodies of cholera patients as suitable material for blind pharmacological and other experimentation seems to the writer as irrational as it is inhuman; nevertheless, perhaps in desperate cases apparently desperate means are allowable, provided always they be neither cruel nor irrational.

Treatment During Reaction.—If the patient rallies from his collapse and enters with a flickering flame of uncertain life upon the period of reaction, the great value of careful nursing and strict diet is, if anything, more apparent than ever before. Drugs avail little or nothing. Small doses of opium are sometimes given with advantage, but as a general thing the patient will fare better without narcotics. Solid foods are absolutely dangerous. Fluids, however, may be allowed somewhat liberally. Milk at first diluted with plain water or carbonic acid water, egg-water, decoctions of arrowroot, sago, or rice well strained and seasoned with plenty of salt, are all to be commended. After a few days, broths and soups thickened with oatmeal, rice, barley, or farina may be allowed. Coffee and tea may now also be permitted in a more concentrated form. Gentle stimulation by generous wines will be found necessary in many cases. Only very gradually, however, can a diet consisting of soft-boiled eggs, meats, concentrated soups, bread, and potatoes be resumed.

Relapses are to be treated with the same caution and on the same principles as the primary attack. When it is remembered that the brunt of the battle had to be borne by the gastro-intestinal tract, the pedantic supervision of the patient's diet will appear not only pardonable but absolutely essential.

Again, in *the management of complications and sequelæ*, the fact should not for a moment be lost sight of, that just as in typhoid fever, so too in cholera, the healing of intestinal lesions must not be jeopardized by a careless allowance of too much or improper food. Lebert says truly, "Indigestion is as fatal in the convalescence of cholera as in typhoid fever."

Having pointed out the necessity of keeping in mind the weakened condition of the gastro-intestinal apparatus, it appears unnecessary to burden this account with detailed directions concerning the treatment of the various morbid states that complicate or follow an attack. The intelligent practitioner will apply the same general principles to this task that guide him in the management of those conditions when not connected with cholera.

The typhoid stage is properly a complication or sequel of the period of attack, and a more or less profound renal disturbance is generally the dominant symptom of that condition. If hot drinks and the induction of perspiration by the use of the wet pack and warm blankets do not relieve the kidneys, it is only exceptionally proper to try more energetic remedies, such as diuretics and pilocarpine. If the patient does not pass any urine within thirty-six hours after reaction has commenced, Macna-

[1] American Journal of the Medical Sciences, January, 1854.
[2] Du Traitement Rationnel de la Periode aiguë du Choléra Asiatique. Paris, 1884.

mara is in the habit of prescribing the tincture of cantharides as recommended by Dr. Francis. He gives ten minims in an ounce of water every half-hour until six doses have been taken. He adds: "If this treatment does not cause urine to pass, we must, after the sixth dose, discontinue the medicine for twelve hours, and then repeat it in precisely the same way, giving six doses more, ten minims each. . . . I have seen this treatment followed by the most satisfactory results in very many cases." Finally, the cautious exhibition of digitalis, which is also a heart-tonic, should not be overlooked at this period.

THE INTERNAL USE AND DOSAGE OF LYSOL.

By ERIC VONDERGOLTZ, M.D.,

NEW YORK.

In view of the menacing epidemic of cholera, I regard it my duty to record my results with lysol in dysenteria and cholera nostras. I used lysol in doses of 3.0 to 10.0 grammes, used in one per cent. strength as clysmata. The astonishing results obtained by this means lead me to ask the profession to combat cholera and its relatives by this method.

The administration of lysol was always combined with that of a stimulant.

As stated in the *American Journal of Obstetrics*, vol. xxv., No. 2, 1892, I have been engaged with the investigation of the antiseptic properties of lysol since October, 1890. By the different experimentators and myself it was found that, relatively, lysol is a harmless drug in comparison to the other powerful antiseptics. I gave the remedy in cases of infectious disease—first in scarlet fever.

The following are the histories of the three most interesting cases:

May 11th I was called to the family of G——. The three children were seized with scarlet fever, presenting nearly the same symptoms. The most alarming symptom was the high temperature, in all cases 103.5° F.; the children also had all the other symptoms relating to the throat, lungs, tongue, eyes, and nose.

The urine of the two elder children showed much albumin and traces of sugar.

The conditions, especially of the eldest child (girl of seven years) and of the babe (fourteen months old), were very critical. The second child, a girl, five years of age, did not seem to be as ill as the others.

I was not misled by my expectations of the internal antiseptic action of lysol. I gave it with sherry wine in the proportion of lysol 5.0 to vin Xeres 10.0. Of this I ordered ten, five, and three drops, for the three children respectively, to be given in milk four times a day.

The effects of these small doses of lysol could be seen within the first twenty-four hours. I saw the children twice a day to May 16th, so I am enabled to give up to that date a complete temperature record.

Analyzing first the curve of M. G——, seven years of age, I have to state that this child got forty drops the first day, with an increasing dose of five drops daily. The temperature fell steadily, without any recurrent exacerbation, till the morning of May 15th, after which no change could be seen.

During the whole time the urine was examined with a double object, viz., to see the effect on the albumin, and note whether phenol could be found. No trace of albumin after the first twenty-four hours could be discovered. The urine showed only one time the presence of sugar, the reason of which phenomenon I could not make out. All the other times the analysis was negative in every respect.

The decrease in the temperature curve can be seen more clearly in the cases of the two other children. The explanation of this fact will probably be that the doses of five and three drops were, in comparison to the age, larger than the ten drops of the older child.

On the second day the temperature of the five-year-old child rose from 98° F. to 99° F. at 6 P.M., which was the result of the neglect of the mother to give the lysol.

On the fourth day the temperature of the baby rose from 98.5° F. to 100.5° F., but this was explained by the fact that the mother gave her some beer.

These two incidents teach two things: 1, that the use of lysol must never be abandoned until the temperature has been normal for a few days; 2, that the diet has to be as restricted as possible, so that no irritation to the uropoetic system may result.

The mixture of lysol, one part, and sherry wine, two parts, could be taken very well in warm milk.

If now, finally, I should formulate a treatment concerning the cholera Asiatica out of these preceding observations, I would advise: 1, To give immediately a stimulant mixed with lysol, 2.5 grammes; 2, to wash out the intestines thoroughly with a one per cent. solution of lysol in warm water. This should be repeated every two hours until a change is seen.

193 SECOND AVENUE.

Progress of Medical Science.

Chronic Heart Disease.—In a paper on this subject in the *Birmingham Medical Review*, Nos. 1 and 2, 1892, Dr. James Little groups the causes of suffering in cases of cardiac disease under the following heads: 1, Overdistention of the cardiac cavities, and particularly of the right auricle and ventricle; 2, inefficient systole in consequence of diminished power or of irregularity in either one or both ventricles; 3, defect in the organs which work along with and help the heart to send the blood through the systemic and pulmonary vessels; 4, disturbances of the innervation of the heart, which may be of cerebral or spinal origin, or may arise from overloading of the stomach, distention of the bowels, or affections of the genito-urinary system; 5, an unhealthy condition of the blood, which may be either imperfectly depurated, as occurs in gout and Bright's disease, or abnormally watery, as in the various forms of anæmia. When over-distention of the cardiac cavities exists, the author advises the abstraction of blood by leeches, the administration of calomel, and restriction of the amount of liquid drunk. When the trouble is due to inefficient ventricular contraction tonics are useful, among which digitalis takes the first place. Dr. Little contrasts strophanthus and digitalis as follows: 1, Digitalis is far the more frequently useful of the two; 2, if a slowing and steadying of the heart has been produced by digitalis, it is often advantageous to keep up its action by an occasional dose of the same remedy; 3, there are some patients whom digitalis sickens, and a smaller number in whom, though the drug does not sicken, it nevertheless fails to bring about an increase in the force of the cardiac contractions, and in such cases we may often produce by strophanthus the effect the older remedy was powerless to accomplish. Patients who have marked thickening of the smaller arteries are sometimes much more benefited by strophanthus than by digitalis; 4, strophanthus is more rapid in its action, but is not suitable for prolonged use. In some cases the effect of this drug is most gratifying, and the author says that he has never seen a failing heart so quickly roused as after the administration of ten minims of tincture of strophanthus and a teaspoonful of brandy in a cup of hot black coffee, repeated twice at intervals of four hours.

Sanitaria for the Care of Consumptives.—Dr. A. Tucker Wise asserts in his monograph on the "Alpine Winter in its Medical Aspects," concerning the advantages of the institution's treatment of phthisis, that, after more than ten years' experience of the treatment of phthisis in the Alps he holds the opinion that "continuous medical supervision of the invalid in a small hotel sanitorium is one

of the best means to be selected for the cure of consumption in its early stages, or the prolongation of life in more advanced phases of the disease, and for training the patient in ulterior self-guardianship."

Treatment of Chloroform Syncope.—The method of treating cases of chloroform syncope resorted to in the clinique of Professor Koenig, of Göttingen, is said to have given very good results. It consists in applying manual compression over the cardiac region some thirty or forty times a minute, the thorax, as a whole, being compressed at regular intervals, by another assistant, in order to facilitate respiration. This compression is said to empty the right ventricle, which in these cases is engorged with blood, and thus to bring about a return of the circulation. Professor Koenig's assistant, Dr. Maas, recommends pressure more frequently repeated, and at much shorter intervals, and by this means he succeeded in reviving two patients who had shown no sign of improvement under the original plan. The operator stands to the left of the patient and presses the thumb deeply at a point midway between the apex beat and the edge of the sternum, repeating the process about one hundred and twenty times a minute. Almost at once the dilated pupils contract, and the presence of an artificial carotid pulse can be felt. After a time spontaneous respiratory efforts are noticed, which are the signal for discontinuing the pressure and the artificial respiration, so long as the contraction of the pupils is maintained and the respiratory efforts do not again cease.—*Medical Press.*

Evacuant Treatment of Cholera.—Dr. George Johnson calls attention again to his castor-oil treatment for cholera. The arguments on which he favors the evacuant treatment and condemns the use of opiates and astringents are certainly plausible. When Koch was carrying out his experiments with the bacillus of cholera he failed to produce the disease in animals by introducing the cholera bacteria into the stomach unless at the same time he injected into the peritoneal cavity a narcotic dose of tincture of opium, his object being "to render it possible for the comma bacillus to remain longer and gain a footing in the intestine." In this manner he induced fatal cholera in thirty out of thirty-five guinea-pigs experimented upon. The administration of opium in cholera would certainly appear to be imitating on the human subject the experiments which Koch and others have performed on guinea-pigs. It is a matter of common experience that the abrupt arrest of diarrhœic discharges is apt to bring about a condition of collapse, and there is no *a priori* reason why this clinical fact should not apply to the diarrhœa of cholera. We know for certain that the opium treatment has invariably and everywhere failed to influence the mortality, and for this reason, if for no other, one would be tempted to try an alternative plan. Even if Dr. Johnson has not succeeded in placing his method of treatment on a sure basis, he has certainly demonstrated the futility and the danger of brutally bottling up the intestines by opiates.—*Hospital Gazette.*

The Treatment of Pneumonia by the Artificial Production of Abscesses.—Prof. Fochier believes that when suppurative processes have taken place in internal organs the disease may be relieved by producing elsewhere artificial abscesses, which may be evacuated surgically. These abscesses he produces by injecting essence of turpentine into the deltoid or hypogastric regions. Dr. Bard contributes the details of a very serious case of pneumonia where such injections had been used with success. His patient, a tailor, aged forty-nine years—a man of good constitution, but of rather alcoholic habits—came into hospital on the tenth day of an acute pneumonia, with consolidation of the upper two-thirds of the right lung. Temperature, 103.6° F.; viscid, amber-colored sputa; weak pulse, atheromatous arteries, and in a state of considerable weakness and danger. A small injection of turpentine was made into the right shoulder; there was some smarting, and two hours later a good deal of pain in both shoulders and arms, with redness and swelling, but the pain soon ceased. The patient went to sleep, and felt much better next morning. The temperature did not sink below 100° F. till the third day after the injection, but after that it did not rise again. The lung cleared up quickly, and no further symptoms showed themselves. On the fourth day after the injection the abscess in the deltoid was opened; it was large and deep, but healed quickly. The patient left hospital quite well. M. Bard believed that the injection had been the starting-point of the successful resolution of the lung. M. Dieulafoy gives an account of the use of the same method in the case of a woman of forty-seven, who had severe pneumonia, following on influenza, with much danger of complete collapse. He gave four injections of fifteen drops of turpentine into the shoulders and thighs, which caused sharp pain for about two hours. In about twenty-four hours improvement commenced, and recovery ensued. The abscesses were opened, and the pus was found sterile. Dr. R. Lépine has employed the same method in one case. Although at the time of the injections the case seemed hopeless, improvement soon took place, and ended in recovery. Fochier believes that the artificial abscesses check the inflammation in the lungs by "fixing" it elsewhere, and calls them "abcès de fixation." Chantemesse and Guigeot prefer the theory that the abscesses do good by causing leucocytosis and bringing up additional leucocytes (phagocytes) to assist those already struggling with the pathogenic organisms in the lungs.—*Dublin Journal of Medical Science*, September, 1892.

Bonuzzi's Treatment of Locomotor Ataxia.—The patient lies upon his back, with a pillow under his head. The doctor then taking hold of the patient's ankles forcibly flexes his legs at the hip-joints as much as possible; the knees are kept extended throughout. Thus the spinal column is strongly bent, and experiments show that the effect on the spinal cord produced by this method is three times as great as the effect produced by suspension. The other advantages of this method are that there is no mechanical apparatus necessary, and the amount of force can be accurately gauged. On the other hand, care must be taken not to flex the legs too strongly, for if too great force be used pain may be caused in the back, and swellings at the back of the thighs, due to intra-muscular hemorrhage.—*Dublin Journal of Medical Science*, September, 1892.

A New Opening for Medical Men.—An English paper of recent date contains the following remarkable advertisement: "*Post-mortems.*—John Briscoe, Esq., M.R.C.S., Carlton Hill, Leeds, has very kindly consented to make post-mortem examinations of animals and birds other than cage birds (which are already undertaken by a very competent gentleman). Subjects intended for examination must, in all cases, be sent direct to Mr. J. Briscoe as soon after death as possible, and accompanied by full particulars as to the date of death, symptoms during illness, treatment, and any other details which are likely to assist the investigator." As the *Hospital Gazette* truly says, the possibilities of this pursuit are immense if properly worked.

The Perils of the Keeley Practice.—An American has recently been released from jail in Mexico where he had been spending the past four months. He had been a sheriff in his native county, but set up in Mexico as a specialist for the cure of whiskey, opium, and other habits. A Mexican opium-eater came to him for treatment, but unfortunately died after receiving a hypodermic injection by the "specialist." The latter was thereupon charged with murder, and his arrest followed. He has now gone home, and will run for sheriff again at the next election, for he thinks it a safer business.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, September 24, 1892.

OUR CHOLERA VISITATIONS.

THE assaults of cholera upon America began in 1832, the original epidemic having started three years before this. The disease attacked New York and spread south and west. New Orleans was in this year affected by both yellow fever and cholera, and the death-rate reached 147.10 per 1,000.

The next epidemic, starting in 1845 in India, reached New York and New Orleans in 1848. The disease was kept out of New York, but it successfully invaded New Orleans and extended up the Mississippi River. Next year (1849) it broke out in New York and was fatal to 5,000 persons.

The third epidemic was brought to New York by emigrants in 1853. It killed 2,000 persons and spread throughout neighboring States. The disease became almost endemic in New Orleans, lasting from 1848 to 1857.

A fourth epidemic started in 1864, and reached this country in 1865. It entered Halifax, New York, and many Southern seaports. The deaths from it in New Orleans in 1866 were 1,294. In the next few years the disease prevailed in many of the Western and Southern States.

The fifth epidemic reached this country in 1873. New York escaped, but New Orleans and some Western cities were less fortunate.

A sixth epidemic started in 1881, reached Western Europe in 1883–84, and tried unsuccessfully to invade the United States.

It will be seen that it takes about three years for the cholera to get from India to the United States. It is brought here by the unwashed classes, and may be carried in the baggage. The years of assault were 1832, 1848, 1853, 1865, 1873, 1884, and 1892. There is no regularity or periodicity in the attacks. If the disease is kept out one year, it may hang about and get in the next.

New York has never had a severe epidemic, and the quarantine officials have kept out the disease three times out of seven. Everything in our past municipal history leads to the opinion that New York can never be severely visited by the cholera.

The city was never in a better condition for resisting the plague. The streets are remarkably clean, the health of the inhabitants is good, and every possible precaution has been taken to stamp out the disease. Even in the few cases that have thus far occurred there have been no secondary ones.

EFFICIENT DISINFECTION.

WE think it quite probable that in time public disinfection will follow very much the course of surgery, and gradually abandon germicidal specifics for simple cleanliness and boiling water. The criticisms which may be made on commonly recommended disinfectants are very well set forth in the *Journal of the American Medical Association*, which says: "A sulphate of iron solution in the strength of $1\frac{1}{2}$ part to 8 of water is advised for the disinfection of cellars, yards, stables, cesspools, sewers, and so on. Accurate bacteriological work has proven beyond doubt that this substance has feeble disinfecting powers at the best, and is altogether valueless in the manner recommended.

"A zinc solution made by dissolving 4 ounces of sulphate of zinc and 2 ounces of salt in 1 gallon of water, is directed to be used for disinfecting clothing, bed linen, and so on. It has never been shown by anyone that this has any disinfecting power whatsoever. In the latter part of the circular it is directed to boil clothing in this solution. While this, of course, is an efficient measure, what advantage is there in this fluid over pure boiling water? It has been shown that boiling soda solution acts more quickly even than pure water, but no such proof has ever been given of the efficacy of the zinc solution.

"Corrosive sublimate solution, 1 to 1,000, is likewise recommended. But the strong germicide properties of this substance are counterbalanced by its tendency to form precipitates with albuminoids and other organic material, and direct experimentation has shown that it is not a reliable agent for the disinfection of discharges."

We have ourselves frequently commented upon the demonstrated inutility of sulphur fumigation. Nevertheless, it is one of the recognized methods of disinfection adopted not only by local, but by national, quarantines. Solutions of bichloride of mercury are also standard disinfectants at national quarantine, and even at New Orleans, where such great claims are made of sanitary perfection.

Heat, lime, soft-soap, and water are the only disinfectants which at present quite escape modern criticism.

A VOICE FROM THE SOUTH.

CHOLERA infected New Orleans in 1832 and killed nearly one-tenth of the inhabitants. It appeared again in 1848 and lasted fifteen years, killing 10,000 people. It came again in 1865, and lasted till 1880, killing over 2,000.

However, the New Orleans sanitarians believe they have learned so much by experience that they can instruct the rest of the country; and we are hearing from the Delta some violent invectives directed against New York's health officials. The *Times-Democrat* publishes a two-column article, by Dr. Joseph Holt, which consists mostly of ravings about New York's politics, lack of scientific knowledge, official lies, and general incompetency. Being pinned down by a request for some practical suggestions for the improvement of New York, Dr. Holt mildly suggests the following:

"The first thing for New York to do, in responding to her obligations, is instantly to dismiss her entire quaran-

tine medical staff. When a quarantine physician, being a State officer, becomes insolent and disobedient, all confidence in him perishes, and he should officially perish with it.

"The next thing for New York to do is to put able and energetic men in those positions, and then go to work and construct a modernized quarantine upon a strictly scientific basis, and enforce it upon rich and poor alike. That discrimination between rich and poor in treatment betrays the pitiable worthlessness of the affair as a scientific institution."

"Doctor, what do you consider the chief essential in a system of sanitary protection?"

"Integrity! When boards of health and quarantine stations cease to be occupied by wire-pullers and mere political accidents, a surprise to themselves and their friends because of the incongruity of their elevation; when these health bodies are a pleasant odor, and not tainted with the doubtful but villainous smell of a secret deal, or other like monetary transactions, and the dead fly ceases to stink in the pot of ointment; when able men, trustworthy and true, occupy these vital stations, without regard to politics or other consideration than peculiar fitness, then confidence becomes the established foundation."

We have sometimes wondered why, if Dr. Holt were such a marvel of sanitary knowledge and integrity, the good people of New Orleans do not keep him at the head of their quarantine system. Is there such a thing as politics in New Orleans?

CHOLERA AND THE SECTION IN PUBLIC HEALTH.

While it is as difficult to advance original ideas concerning cholera as to suggest a novel theory in regard to Hamlet's character and peculiar frame of mind, it may prove profitable to present anew ideas already existent, that apprehension may be transformed to easy security through greater knowledge and more intelligent precaution. Such evidently was the aim of the New York Academy Section in Public Health, which held a meeting of peculiar interest, September 19, 1892. Suggestions, varied as the temperament of the speakers, and all sound in the main, were listened to by a numerous and intelligent audience, who had come to mark, learn, and inwardly digest whatever experience could give in the way of advice. One physician advocated a permanent national quarantine, to be given into the hands of the Marine Hospital Service, who already do part of the work. Another suggested that every ship's company should have a clean boat in port during an epidemic of cholera, to which persons from an infected vessel could be at once transferred on arriving. Every well person, every sick passenger, the dying and the dead, should be removed promptly from infected steamers. The question of cholera hospitals was answered in the negative, on account of danger in moving the patient. The pauper on a pallet of straw, it was said, stands a better chance of recovery in squalor, if he only has an attendant to give him plenty of cold water to drink and put hot bricks around him as occasion requires, than if transported to the most luxurious hospital after the disease is definitely developed. Disinfection of excreta, and prompt attention to the early diarrhœa among persons otherwise free from suspicious symptoms, has stamped out an epidemic in four days, and may reasonably be expected to do so again. The cleanliness that is next to godliness, as far as cholera is concerned, consists in a perfectly clean and much white-washed cellar, wood-work washed with proper disinfectants, ideal plumbing, the steaming of carpets, hangings, and upholstery, the ripping apart and steaming of hair mattresses and pillows, free ventilation and plenty of sunshine. The best disinfectants are carbolic acid, chloride of lime, corrosive sublimate, and sulphur. Air and sunshine have power to render the cholera germ innocuous in time, while sufficient heat destroys it always. The army and navy surgeons appeared to think but little of cholera in any of its aspects; for, as one of them said, familiarity with its management had necessarily bred contempt for its dangers.

CHOLERA INOCULATIONS.

Now that the daily newspapers have taken up the subject of cholera inoculations and are sending correspondents to test their preventive efficacy *in corpore vilo*, it is well to recall the fact that Ferrán practised them in the south of Spain some seven years ago. The first experiment was made on February 23, 1885, Dr. Sereñana, an assistant of Ferrán, having been inoculated in each arm on that date. Three hours after the injection he had a severe pain in the posterior part of each arm, and at the end of seven hours had a slight chill with some elevation of temperature and a rapid pulse, and complained of a moderate headache. At the end of twenty-four hours all these symptoms had passed away. Another inoculation, nine days after the first, was followed by negative results. In the epidemic which occurred the following summer, Dr. Ferrán and his assistants made a very large number of inoculations, and the claim was made, and supported by elaborate statistics, that the inoculations were really preventive, the morbidity and mortality among the vaccinated being markedly less than in the unprotected. The author of the method met very naturally with much opposition, both at home and abroad, and he seems to have been unable or unwilling to contend against it, for since the publication of his statistics, at the close of the epidemic of that year, nothing more has been heard of his inoculations, and even the Spanish papers make no claims for priority on his behalf.

Duration of Treatment in Syphilis.—Dr. Heilmann has noted the time required, under different methods of treatment, for the disappearance of the first symptoms in syphilis. He compared treatment by calomel injections, mercurial frictions, and mercury by the stomach, in 843 cases of recent syphilis without complications and without previous treatment, and found the mean duration of treatment was 49.8 days. The smallest mean duration was 41.4, furnished by subjects ranging from sixteen to twenty years of age. For those between twenty-one and thirty years the average duration was 47.5 days. Women required a longer treatment than men. The average of treatment by calomel injections was 46.6, by mercurial inunctions 51.1, and by mercury internally 56.6.

News of the Week.

Cholera up to Date.—At the time of writing it is twenty-one days since the first cholera ship, the Moravia, arrived in this port. Among the ships there have been 163 cases and 98 deaths, only 22 of which occurred in this port. Besides this there have been eight cases and six deaths in the city limits.

The Jews and Cholera.—The Hebrew race is periodically reported to be exempt from the serious ills of humanity ranging from gonorrhœa to cancer. It is now asserted that the Russian Jews have been "miraculously" spared in the epidemics of cholera in Russia and at Hamburg. Unfortunately, the official statistics do not in the least bear this out.

The Mortality from the Cholera in New York, in 1832, was 3,200; in 1849, 5,000; in 1853, 2,000. The mortality from cholera in New Orleans, from 1832 to 1880, was 17,187 (Jones). The mortality-rate is given usually as not under one-third or over one-half. In Berlin the mortality-rate was 65.8 per cent., or 18,916 deaths in 28,753 cases, from 1832 to 1873 (Eichhorst). In New Orleans the mortality-rate, from 1842 to 1880, in Charity Hospital, was 67.3 per cent. (Jones).

The cholera mortality, therefore, seems to be in fact over fifty per cent. as a rule. The aged, the debilitated, and the intemperate are most liable to succumb.

Curious Prescriptions for the Cholera.—In 1832 an ingenious American physician proposed to check the diarrhœa by plugging the anus with a soft velvet cork. An English physician, even more ingenious, proposed to keep the blood circulating by putting the patient on his back on a board, and see-sawing him up and down at the rate of eighty to one hundred times a minute. Another physician advised bleeding, turpentine, and cool drinks; still another thinks the disease one of the spinal cord and sympathetic, and plasters the back with ice-bags.

Treatment of Cholera.—The famous elixir of Voronej, widely used in Russia, is composed of the following ingredients:

℞. Ammon. muriat. ..... ʒ x.
Olei naphthæ. ..... ʒ vj.
Olei caryophilli. ..... ʒ x.
Acid nitric. ..... ʒ vj.
Potas. nitrat.,
Turkey pepper. ..... āā ʒ jss.
Menth. virid. ..... ʒ viij.
Aceti. ..... Oj.
Spirit. vini gallic. ..... Oiv.
M.

A Corpse in a Medical College.—A prominent lawyer of this city relates the following somewhat extraordinary story. He says: "I had a most extraordinary relation with General Harrison a good many years ago. I don't suppose a case of that kind ever happened before, or ever will happen again, affecting a family of such distinction and involving two Presidents of the United States. We have in Cincinnati medical colleges which utilize dead bodies for subjects for the use of medical classes. At North Bend or Cleves had died a young woman, and soon after her decease it was found that her grave had been rifled of her remains. Making further search, it was found that the body of Benjamin Harrison's father was also missing. President Harrison's brother came down to Cincinnati, suspecting that these bodies had been sold to the medical college, and he got authority to examine the places of deposit of fresh subjects. At one of these colleges they had certain bodies put in a well, and there pickled, you may say, so as to have them in a state of preservation for the dissecting-table. The president of the college was a well-meaning man, and he had not the least suspicion that anything would be found in the possession of his institution reflecting upon an historical and respectable family. But when they ran down a hook to bring up the successive corpses, the very first one that came up was venerable Mr. Harrison, father of Benjamin Harrison, our President, and son of William Henry Harrison, also our President. It was certainly a dreadful sight for a son to see his father appear suddenly in that state. General Harrison came down from Indianapolis to Cincinnati. I believe that he would have killed the president of that institution, if he could have found him at that time. He was inflamed, as he well might be, at the indignity visited upon his beloved parent, one of the most inoffensive men in all that country, and a man of fair distinction too, who had been offered the Lieutenant-Governorship of Ohio, and sent to Congress. He turned about and came to our firm, and employed me and my partner to prosecute the college. Nothing could be done, however. In all respects of outrage it would look as if a crime had been committed, but in point of fact, nobody but the obscure perpetrator of the grave-robbing could be prosecuted. The body was returned to the tomb, and the family were left to let time heal their wounded feelings."

An Army Medical Board will be in session in New York City during October, 1892, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the board will make application to the Secretary of War before October 1, 1892, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the board. Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

The Epidemic at Hamburg: Its Explanation.—Hamburg, which had been poisoned by immigrants and sailors from Russian ports, had unhappily presented filth conditions not inferior to those which had invited the devastations recently of Russia, and of late years of Naples, Sicily, Spain, Marseilles, Toulon, and the mild outbreaks of Paris, all epidemics spread by filth in water and soil, of which Mr. Ernest Hart stated he could give, if time allowed, exact authentic and fully admitted details.

Most of those cities had learned the lesson and taken it to heart more or less completely; to the extent to which they had done so they would have relative immunity in the future. Hamburg had not; the Elbe was filthily polluted, and it furnished the drinking-water of the city, very ill-filtered or unfiltered. The drinking of the water, except after boiling, had now been strictly forbidden, and the river baths were closed. According to the extent to which these edicts were rigidly enforced and carried out, the present epidemic would be limited and rapidly decline. This would do more than the "sprinklings" with tons of disinfecting powder and "vague libations" of thousands of gallons of antiseptic fluid, of which much had been heard during the last few days. Hamburg had sinned against natural laws, and was unhappily paying the penalty in suffering: "The soul that sinneth it shall die."—Ernest Hart.

The English View of It.—Quarantine may be defined as an elaborate system of leakiness; impossible if it be complete, because implying isolation and arrest of intercourse; useless and dangerous if incomplete, because inviting a false reliance and offering a false security. Medical inspection, with the powers of detention, was a more real precaution and more easily made effective; but under the circumstances it was only a sieve, which would strain off the coarser majority of cases, but through whose many apertures the more subtle were already passing, and would pass.

The Second International Congress of Physiologists.—The Second Triennial International Congress of Physiologists has this year held its sittings at Liège, with Professor Holmgren (Upsala) as President, in the Physiological Institute of the University. The Congress terminated on Thursday, September 1st, after a banquet at which the Burgomaster of the city was present. More than one hundred European physiologists attended the Congress; of these, twenty-four represented Great Britain and Ireland, the number of British members being larger than at the Congress at Basle four years ago. Professor Michael Foster and Professor Burdon-Sanderson were present. The following communications were read by the British members and illustrated for the most part by experimental demonstrations: On the first day: "Nucleo-albumins," by Professor Halliburton, of London; "The Fate of Peptone in Blood and Lymph," by Dr. Starling, of London; "The Action of Antagonistic Muscles under Reflex and Cortical Excitation" (demonstration), by Professor Sherrington, of London. On the second day: "Some Further Experiments on the Frontal Lobes," by Professor Schäfer, of London; "Crystalline Globulin from Urine" (demonstration), by Dr. Noel Paton, of Edinburgh; "Varieties of Leucocytes" (with demonstration), by Professor Sherrington; "Structure of Striated Muscle" (with demonstration), by Professor Schäfer; "Cortical Centres for Movements of the Anus and Vagina" (demonstration), by Professor Sherrington. On the third day: "Temperature and Excitability" (with demonstration), by Professor Gotch, of Liverpool; "The Depressor Nerve," by Dr. Bayliss, of London; "The Capillary Electrometer and Observations on Muscular Contraction," by Professor Burdon-Sanderson and Mr. Burch (Oxford); "Myothermal Observations upon Man" (with demonstration), by Dr. Waller, of London. It was agreed to hold the next Congress in 1895, at Berne, in the Physiological Institute of the University, under Professor Hugo Kronecker. The general secretaries chosen for the next Congress are: For the French language, Professor Arloing; for the German language, Professor Exner; for the English language, Professor Sherrington.

Measures of Precaution Adopted in Nursing Cholera Patients.—The precautions in cholera nursing are essentially the same as for nursing typhoid fever, only more rigid and severe, as the disease is more virulent. The following rules were enforced and disinfectants employed at the London Hospital at the time that Mrs. Gladstone nobly gave her services, and the sisters of All Saints, Margaret Street, aided the hospital so successfully: The first two or three days Condy's fluid diluted, and chloride of lime; subsequently carbolic disinfecting powder and carbolic acid largely diluted (1 to 40), mixed with sawdust in quantities sufficient to wet the sawdust and sprinkle about the passages, wards, closets, etc. None of the excreta from patients was allowed to be emptied into the sewers; instead of this a portion of dilute carbolic acid fluid—about half a pint—was put into each chamber-pail, and buried in the garden. The pails had water-tight lids. Burnett's fluid was sprinkled in the cabs that brought the patients. The straw from the beds was burnt in each case of death, or where much soiled by excreta. The linen from the cholera wards was washed separately in the laundry of the hospital with McDougall's disinfecting soap. Hot coffee, beef-tea, etc., were recommended to be taken by the nurses at early dawn, and every one was advised to avoid going on duty with an empty stomach, or in a depressed condition. An extra allowance of wine and pay was made to the nurses.—*British Medical Journal.*

A Code of Effective Cholera Precautions for Doctors and Nurses Observed in 1885.—Although cholera raged so severely in Chili in 1886–87, the doctors and nurses in a number of small hospitals in different localities of the town were enabled entirely to protect themselves. Each of the hospitals contained from fifty to sixty beds, and had a staff of six doctors, six students, and thirty attendants. All wore long aprons, reaching from the chin to the feet, and caps. For washing the hands and face a solution of corrosive sublimate (mercuric chloride, 1 to 1,000) was exclusively used. In the dining-room all dishes before being used were strongly heated by the flame of burning alcohol. The bread was sterilized by toasting. It is stated that no one of the staff sickened who adhered rigidly to these precautions. The convalescents before their discharge were bathed in the corrosive sublimate solution, and their clothing was washed in a similar disinfecting solution. The floors of the hospitals were made of a kind of pine parquet soaked in tar, and were washed daily with a solution either of copper sulphate or potassic permanganate, 1 to 1,000. On emptying a ward it was fumigated according to rule by sulphurous acid gas for twenty-four hours.—*British Medical Journal.*

Preventive and Curative Drinks and Medicines.—Put not your trust in nostrums; cholera does not "come by Providence and go by medicine," although that is a common and ignorant belief in respect to it and many other

diseases. A tried and safe preventive of the tendency to diarrhœa (which should always be checked) is sulphuric acid lemonade, made by acidulating boiled and sweetened water to taste with dilute sulphuric acid (or, as at the Post Office, Dr. Waller Lewis's very palatable sulphuric orangeade). The citric acid lemonade lately vaunted was rather inferior in value to this. The cholera bacillus, as we now know, was favored by an alkaline fluid, and did not live in acid media. An excellent and well-tried preventive of the prevalent slight diarrhœa was the Vienna mixture (used in barrels formerly in hospital practice). It consisted essentially of 15 drops of dilute sulphuric acid to 6 ounces of boiled and sweetened water, to which might be added, under medical advice, 10 drops of sulphuric ether and 5 drops of laudanum for an adult. On ice-bags, camphor solutions, and other expedients of the kind no reliance could be placed, except in skilled hands and for selected cases. Many people poisoned themselves with camphor during a late epidemic, as a precaution against cholera. Once established, and in well-marked cases of Asiatic cholera, drugs would do little to cure. The mortality of cholera all over the world and in all epidemics had defied drugs—just as severe arsenical poisoning would do—and varied according to intensity and the age and condition of the patient from forty-five to sixty-four per cent. It was eminently a case in which prevention was far more efficacious than cure.—Ernest Hart.

Sir Joseph Lister, having attained the age of sixty-five, has been retired from the Chair of Surgery, at King's College Hospital.

Dr. Hobart A. Hare, of Philadelphia, has undertaken a research into the action of chloroform, on behalf of H. H. the Nizam of Hyderabad's Government.

The Cholera Abroad.—If the official reports from Europe are to be believed, the epidemic of cholera in the Russian cities and Hamburg is beginning to subside. Most of the cases in the latter city are from the districts of Horn, Hamm, Barmbeck, and Hammerbrook, where there is to be found the larger part of the tenement-house population. The people there are miserably poor and half starved, and they persistently defy the attempts of the authorities to improve the sanitary condition of their dwellings and surroundings. Refugees are beginning to return to their homes, and there is an evident revival of business in the city. The London correspondent of the *Sun* telegraphs extracts of a letter from Dr. Louis L. Seaman, formerly chief of staff at Blackwell's Island, in which it is stated that the cholera epidemic in Paris is second only to that of Hamburg in its severity, and that the authorities have persistently concealed the facts. There are, he asserts, from eighty to one hundred cases admitted to hospital every day, and the mortality is, as elsewhere, about fifty per cent. Dr. Seaman says that these facts regarding the cholera epidemic have been misrepresented by the press, which is either subsidized or muzzled in the interests of the shopkeepers, whose rich harvests are now being gathered from returning continental travellers.

The Riberi Prize.—The Royal Academy of Medicine of Rome, has announced a prize of $4,000 for the greatest discovery in anatomy, physiology, pathology, or pharmacology during the period from 1892–96. The essay descriptive of the discovery must be written in Italian, French, or Latin, and must be handed in not later than December 31, 1896.

The Congress of German Naturalists and Physicians, which was to have been held this year at Nürnberg, during the week beginning September 12th, has been postponed to next year by reason of the cholera.

Dr. Otto v. Steinau-Steinrück died recently at the age of seventy-three. He was formerly one of the leading physicians of Berlin, but had retired from practice several years ago.

The German Public Health Society.—It has been decided to omit the annual meeting of this society, which was to have been held in Würtzburg this month. The reason given is that most of those who were to have participated in the proceedings are busy fighting cholera, and have no time for talking.

Dr. John F. Dunker died at his home in Newark, N. J., on September 15th, at the age of eighty-three. He was a native of Denmark, and began practice in Newark forty years ago.

The Medical Advisory Committee of the New York Academy of Medicine, consisting of Drs. Stephen Smith, A. Jacobi, D. G. Janeway, T. M. Prudden, R. H. Derby, H. Biggs, and Allan McLane Hamilton, has submitted its report to the Special Committee on Quarantine of the Chamber of Commerce. The report deals with the necessity of disinfecting merchandise and baggage carried in infected ships, of transferring infected passengers from the ship without delay and isolating them in small groups, of thoroughly disinfecting ships and contents with live steam, of denying entry to edibles from infected ports, and maintaining quarantine but five days after the development of the last case. In a general way it indorses the quarantine system and believes that it is possible by proper methods of disinfection to stamp out cholera on an infected ship, when quarantine is impossible, without removing the passengers.

Disinfection of Diarrhœal Discharges.—To Physicians, Nurses, etc.: At a meeting of the Board of Health of the Health Department of the City of New York, held on the 16th inst., the following preamble and resolution were adopted:

Whereas, The presence of cholera in this city and its relation to diarrhœal diseases makes it extremely important that all diarrhœal discharges be at once disinfected, as many cases of cholera take the form of mild diarrhœa, but the discharges in those cases are as dangerous as from the severer types of the disease; therefore

Resolved, That physicians and nurses are respectfully requested to see that this recommendation is promptly carried out, as in this way the great danger of spreading infection from unsuspected cases of cholera will be greatly lessened.

By order of the Board of Health. Charles G. Wilson, *President*. Emmons Clark, *Secretary*.

Reception to the American Gynecological Society.—Dr. and Mrs. John Byrne, of Brooklyn, gave a notable and largely attended reception at their residence, 314 Clinton Street, to the American Gynecological Society, on Tuesday evening, September 20th.

Pecuniary Aid to the Health Board.—A requisition by the Board of Health of New York for an appropriation of $17,500 was honored by the Board of Estimate and Apportionment yesterday. This additional sum is rendered necessary by the extra precautions which have been considered advisable in the provision for the possible outbreak of cholera. Ten thousand dollars is to be expended for temporary hospitals and ambulances, $5,000 for disinfectants, and $2,500 for twenty-five additional sanitary inspectors to be employed for a month. Relief was also granted to the Street Cleaning Department by the passage of a resolution allowing Commissioner Brennan to employ 100 additional men to flush the streets and to trim scows.

Dr. and Mrs. Lewis A. Sayre entertained the American Orthopædic Association at a reception given at their Fifth Avenue mansion, on Tuesday evening, September 20th. A large number of representative medical men and other friends from this and other cities honored the hosts and their guests by their presence.

The Cholera Scare in New York has fortunately abated. The newspapers are necessarily quiet. Scare head-lines cease to appear, no new cases have occurred, the quarantined passengers are properly housed, the Health Board has proved its efficiency, the health officer is no longer blamed, and public confidence is again restored.

Reviews and Notices of Books.

HOSPITALS AND ASYLUMS OF THE WORLD: Their Origin, History, Construction, Administration, Management, and Legislation; with Plans of the Chief Medical Institutions, accurately Drawn to a Uniform Scale, in Addition to those of all the Hospitals of London in the Jubilee Year of Queen Victoria's Reign. By HENRY C. BURDETT, Formerly Secretary and General Superintendent of the Queen's Hospital, Birmingham; the "Dreadnaught" Seamen's Hospital, Greenwich; Registrar of the Medical School; Founder of the Home Hospitals Association for Paying Patients, the Hospitals Association, and the Royal Nursing Pension Fund for Nurses; Author of "Pay Hospitals of the World," "Hospitals and the State," "Cottage Hospitals: General. Fever, and Convalescent, with Fifty Beds and Under," "The Relative Mortality of Large and Small Hospitals," "Helps to Health," "Burdett's Hospital Annual and Year-book of Philanthropy," and Editor of *The Hospital*. In Four Volumes and Portfolio. Volume I. ASYLUMS—HISTORY AND ADMINISTRATION. Volume II. ASYLUM CONSTRUCTION, PLANS, AND BIBLIOGRAPHY. London: J. & A. Churchill. 1891.

IT is difficult in a brief notice to do justice to a work of this magnitude and excellence, and we can only attempt to give an idea of the character of the work and of the thoroughness with which the task has been carried out by the accomplished author. It is hardly necessary to refer to the great value of such a work from an historical point of view, or as a book of reference for all those interested in hospital construction and management. This is an age of scientific hospital construction, and no one at the present day should have a hand in the erection of a building for the housing of the sick or of the insane, who is not only well up in all the principles of ventilation and warming, but also thoroughly conversant with the history of the subject, and in position to profit by the errors as well as the successes of his predecessors.

In the first volume Mr. Burdett gives a historical review of the management of the insane from the earliest times down to the present, and then treats of the present condition of lunatic asylums in different countries of the civilized world, of lunacy laws now in force in these countries, and of asylum nursing and training of attendants for the insane. The second volume deals with asylum construction, furnishing, and appointments, and also contains a number of plans of existing and proposed institutions for the care of the insane and feeble-minded. Not the least valuable feature of this volume is a very complete bibliography of all works descriptive of asylums and of their management. Each volume is furnished with a very satisfactory index. In addition to the plans above mentioned, there are numerous illustrations of furniture and appliances specially adapted to asylum use. The volumes are excellently printed in clear type on heavy paper, and are bound neatly and durably.

The author has done an excellent service to the profession and philanthropists in general, in presenting them with a work of such undoubted utility. We can only add, in concluding this brief notice, that it is a matter of congratulation that so necessary a work has been undertaken by one so thoroughly competent, by long and practical experience, to perform the task satisfactorily as Mr. Burdett.

HOW TO FEEL THE PULSE AND WHAT TO FEEL IN IT. Practical Hints for Beginners. By WILLIAM EWART, M.B. Cantab., F.R.C.P., Physician to St. George's Hospital; Clinical Lecturer and Teacher of Practical Medicine in the Medical School; Physician to the Belgrave Hospital for Children; Additional Examiner in 1891 for the Third M. B. of the University of Cambridge; late Assistant Physician and Pathologist to the Brompton Hospital for Consumption and Diseases of the Chest. With Twelve Illustrations. New York: William Wood & Co. 1892.

IT is a fact that goes without saying that the pulse does not receive half the attention from physicians that its importance indicates. It is a valuable aid in diagnosis and prognosis as well as a meter of the strength of the patient. To obtain these ends, however, it must be thoroughly studied, and its study is quite a considerable bit of science. Dr. Ewart's book fills all the requisites. It is clear, concise, and contains a wonderful lot of knowledge between its covers. Once mastered, the physician will have in the pulse an incalculable aid. The subject is clearly illustrated.

A SYSTEM OF THERAPEUTICS. Edited by HOBART ARMORY HARE, M.D., Professor of Therapeutics and Materia Medica, in the Jefferson Medical College of Philadelphia, assisted by WALTER CHRYSTIE, M.D., formerly Instructor in Physical Diagnosis in the University of Pennsylvania. Vol. III. Diseases of Skin, Nervous System, Genito-urinary Apparatus, Eye and Ear. With Illustrations. Philadelphia: Lea Brothers & Co. 1892.

THIS is the last volume of Dr. Hare's admirable work on therapeutics, reviews of the first two volumes of which have already appeared in the MEDICAL RECORD. The work is one of monumental size, but every detail of it is excellent and it entrenches the Anglo Saxon race in the first rank of therapeutists. Each article is written by an authority on the subject. The original method of taking up a disease and giving the treatment of it to the exclusion of etiology, symptoms, etc., except so far as is necessary, is adhered to. The book is one that should be in every library. Diseases of the skin are treated by H. Radcliffe Croker, W. A. Hardaway, James Nevins Hyde, and Milton B. Hartzell. Diseases of the nervous system receive three hundred and eighty-four pages, and are in the hands of Edward N. Brush, H. M. Bannister, B. Sachs, J. Chalmers DaCosta, M. Allen Starr, Charles K. Mills, Landon Carter Gray, Wharton Sinkler, C. Eugene Riggs, Joseph Ransohoff, T. D. Crothers, and F. X. Dercum. Diseases of the Genito-urinary Apparatus have three hundred pages from the pens of Andrew H. Smith, J. Will-

iam White, Edward Martin, T. J. Watkins, R. L. Dickinson, Hunter Robb, Howard A. Kelly, and Barton Cooke Hirst. Diseases of the eye are allotted over three hundred pages, and the authors of the several monographs are W. F. Mittendorf, George E. de Schweinitz, Charles J. Kipp, S. C. Ayres, Swan M. Burnett, Henry Gradle, Lucien Howe, Edward Jackson, and F. Bueller. Diseases of the ear likewise receive extended attention, the several authors being B. Alexander Randall, Robert Barclay, Samuel Sexton, and Charles H. Burnett.

Du Traitement par l'Électrolyse des Déviations et Éperons de la Cloison du Nez. Par J. Bergonié et E. J. Moure. Paris: O. Doin; et Bordeaux: Feret et Fils. 1892.

In this monograph the causes, symptoms, etc., of spurs and deviations of the nasal septum are briefly given, and full directions given as to the application of electrolysis for their removal. This mode of treatment has received a more cordial welcome among the French rhinologists than among those of any other nationality. In this monograph, clinical histories with illustrations are given to prove the logic of the ground taken. The results obtained by electrolysis have been surprisingly good. In this country, the saw and trephine are mostly used for spurs of the septum, while for deviations several different operations have been proposed. The ultimate result of the latter is often very unsatisfactory. We believe that the next ten years will see electrolysis more frequently practised by American specialists in this branch.

Une Mission en Espagne: L'Hygiène et l'Assistance Publiques. By Dr. C. Delvaille; avec une Préface de M. le Professeur Brouardel, Doyen de la Faculté de Médecine de Paris. Paris. 1892.

This is a general description of the methods of public hygiene in its broadest sense, as existing in Spain at the present time. A full description is given of the laboratories employed in the work, laws in regard to disinfection, public baths, hospitals, dispensaries, etc. It will doubtless surprise many to learn that sanitary science has reached such healthful proportions in a country we are so apt to regard as way behind the times in such matters.

What to Do in Case of Accident. By B. Merrill Ricketts, Ph.B., M.D., International Medical Congress, Washington, D. C., 1887, American Medical Association, Ohio State Medical Society, Fellow of the New York State Medical Association, Mississippi Valley Medical Association, National Association of Railway Surgeons, Cincinnati Academy of Medicine, Cincinnati Medical Society, Southwestern Ohio Medical Society, Cincinnati Natural History Society; Visiting Dermatologist German Protestant Hospital; Physician for Skin Diseases and Plastic Surgery to Christ's Hospital, and Consulting Physician for Skin Diseases to Ohio State Hospital and Woman's Medical College; Chief Surgeon for C. P. and V. R. R., and A. E. and L. Ins. Co. Cincinnati: Printed by James Barclay. 1892.

We have reproduced the whole of the title-page of this treatise as a warning to others who may be tempted to do likewise. The aim of the book is apparently to instruct the layman concerning the course which he ought to pursue when so unfortunate as to meet with an accident, or to be a witness of such mishap to others. The instruction is imparted in the form of maxims, short, sharp, and to the point, as will be seen from a specimen here quoted. The section is headed "Fire," and reads as follows: "1. Locate fire-escapes. 2. Keep still if clothing takes fire. 3. Lay down upon the floor at once. 4. Cover with a coat, shawl, rug, carpet, blanket, or anything at hand. 5. If unprovided, take a full breath and stoop low and crawl along the floor. 6. Jump in the water (ocean, river, lake, pond, tub, etc.). 7. Roll in the snow or mud. 8. Control panic of others. 9. Keep presence of mind. 10. Before passing through fire or smoke, wet a pillow-case, cut an eye-hole, and put it over the head." Much other valuable and interesting information, not strictly medical in its nature, is to be found within the covers of this small work. Thus we read on page 55, that "it is a fraud to conceal a fraud;" on the following page that "America was discovered in 1492;" on page 57 that "a firkin of butter weighs fifty-six pounds," and on page 58 that "whale is said to live 1,000; elephant, 400; swan, 300." Time, space, and the copyright law forbid us to quote further from this instructive work.

The Extra Pharmacopœia. By William Martindale, F.C.S., late Examiner of the Pharmaceutical Society, and late Teacher of Pharmacy and Demonstrator of Materia Medica at University College. Medical References and a Therapeutic Index of Diseases and Symptoms, by W. Wynn Westcott, M.B. Lond., Deputy Coroner for Central Middlesex. Seventh Edition. London: H. K. Lewis. 1892.

Nothing brings more clearly to mind the manifold changes, we do not say advances, in the materia medica than the successive editions, appearing at short intervals, of works of this kind. It is only two years since the sixth edition of this excellent little work was published, yet the additions to the present one have required nearly three hundred new entries in the index. The general arrangement of the material employed is the same as that of previous editions, and, as we have said before, we repeat now, that we know of no more handy and satisfactory little work of reference on therapeutics and materia medica than this. Those who use it in this country must, of course, remember that the preparations and doses are those of the British Pharmacopœia.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PUBLIC HEALTH.

Stated Meeting, September 19, 1892.

H. D. Chapin, M.D., Chairman.

The Present Status of Quarantine Laws and their Administration.—Dr. S. T. Armstrong read the first paper of a series relating to quarantine and cholera.

Quarantine, he said, might be defined as a period of variable length, during which persons coming from localities where epidemic diseases existed were detained for purposes of observation. Inferentially, it included a properly equipped establishment for the reception of the well, hospital for the ill, place for disinfection, a corps of trained nurses, etc.

Among the diseases from which our maritime quarantine was intended to protect us were yellow fever, typhus or ship fever, cholera, small-pox, scarlet fever, measles, diphtheria, and leprosy. The author thought it was superfluous to make any argument regarding the desirability of quarantine. He especially impressed the advantages of national quarantine, free from political influence, which implied permanence of office and extensive experience. That Congress had power to legislate was shown by a decision of the Supreme Court. Meantime we should not underrate the value of State and local quarantine when conscientiously carried out. Congress should enact laws necessary to supplement and complete the authority which it had already vested in the Marine Hospital Service.

How Long Shall a Cholera-infected Vessel be Detained at Quarantine?—Dr. Alfred S. Carroll read a brief paper on this subject. The question could be answered in three words: A few hours. Reasons for this statement were that it had long been known that the cause of

cholera lay in the discharges of infected patients. As a rule, only the uncleanly, or those confined in steerage quarters on vessels, were likely to get the disease. Rarely did cabin passengers need detention. It had not been shown that cholera had ever been transported by merchandise. The danger was only from articles contaminated by the cholera discharges. There was evidence that the discharges were virtually harmless while fresh. Dr. Carroll said that with such doctrine before us the problem of dealing with ships could be reduced to very simple terms. Cholera could be, and had been, stamped out on shipboard in a very short time. When Vanderpoel was health officer a case of cholera occurred in a first-cabin passenger, yet the vessel was detained only twenty-four hours. The dejecta were cared for, the clothing treated, etc., and no further cases developed. But certain rules should be observed: All passengers should be instantly removed from the vessel; the sick should be separated from the well; the latter need be kept under observation only until after the period of incubation had passed. To keep the well and suspected on board was contrary to the dictates of humanity and common sense, and tended to render futile the very purpose of quarantine. In a very short time the vessel's bilge could be washed out, and parts exposed to cholera thoroughly disinfected. Thoroughness did not imply slowness. To avoid a senseless panic it should be known to a certainty whether one had to deal with real Asiatic cholera, and this could now, or in the past, be determined by the clinical history and post-mortem appearances, without waiting several days for a bacteriological examination.

Dr. G. M. Sternberg then read a paper on "The Biological Characters of the Cholera Spirillum, and Disinfection in Cholera," which will appear in a future issue of the Medical Record.

Sulphur Dioxide as a Disinfectant.—Dr. J. H. Raymond weighed the evidence bearing on the value of this agent as a disinfectant, especially in cholera. It had been used as a disinfectant for three thousand years. But since bacteriological research had come to take so prominent a place, the questions of disinfection, antisepsis, and deodorization had been studied more scientifically and their dividing lines drawn more exactly. The same disinfectant was not equally efficacious in killing the different varieties of germs.

Sulphur dioxide would destroy spirilla, while it proved a failure as a disinfectant for bacilli in that it would not destroy the spores. Koch had asserted that the spirillum of cholera was without spores, and although this was now being doubted by some, yet actual test showed that the sulphur dioxide, employed in the manner recommended by the American Public Health Association, was an efficient disinfectant against cholera germs carried in rags, etc. The author cited the experiments of Dr. H. M. Biggs, and concluded with saying that sulphur fumigation, while not replacing bichloride, carbolic acid, lime, could be used in conjunction with them, and where steam was inapplicable should be employed because of its power of diffusion.

Local Measures of Prevention and Relief in New York City.—Dr. Stephen Smith read a paper with this title. It was based on his experience in the epidemics of 1849, 1854, and 1866.

Diarrhœa was a premonitory stage of cholera; it was painless, and rarely excited apprehension; it was very curable, not far from ninety-nine per cent. of the cases recovering if properly treated; further, cholera attacked the more insalubrious places, and these by degrees. On these facts he would base the prevention or management of an epidemic as they did in 1866, when it spread from isolated cases in the city, and was prevented in about every instance. The city was divided, by aid of the dispensaries and the Board of Health, into districts, so that physicians visited the homes of the working people, treated all cases of diarrhœa, and reported any case of cholera, which was at once guarded, the inmates of the house kept under strict surveillance for commencing diarrhœa. Disinfection was employed, etc. A similar plan might be adopted to-day. He had observed that to transport patients with well-marked cholera to a hospital, especially any distance, was extremely fatal. They could be safely quarantined in their homes. Separate wards could be used in general hospitals without danger, under proper care, and he regarded this as better than extemporizing hospitals or transferring patients to islands.

The Practitioner and Cholera; Suggestions.—Dr. A. Jacobi thought the most important suggestion which he could make was that the subject had been fully treated of, that the hour was late, and he had better say nothing.

Being urged, he said he would repeat a suggestion he had given to the newspaper reporters, viz., that they say as little as possible of the cases of cholera in town, and print and reprint from day to day in boldest type the circular of the Board of Health. He suggested to practitioners that they also read that circular and see that their patients lived up to it.

It was all very well to read that what water they drank should be boiled; but the doctor should tell his patients to keep it in an aseptic vessel, and that only such water should be used in washing hands and face and mouth. The people should wash their hands, face, and mouth before and after each meal. Physicians should see that the families under their care were not taking some advertised quack medicine which, in their opinion, relieved them of every precaution. They ought to see that diarrhœa and other troubles did not go unheeded as due to dentition. What isolation could do to prevent the spread of cholera had been shown in this city, and the speaker gave great credit to Dr. Bryant in this matter through his connection with the Department of Health. He also expressed praise for the efficiency of the Governor, and said that at the next election he would vote for him, notwithstanding Tammany. Encomium was further due the public-spirited citizens, those who were least likely to contract cholera, yet who, in the face of a threatened epidemic, had in two days raised two hundred thousand dollars to ward it off. It was a duty of the physicians of the city to inspire these noble men with the necessity for like generosity in stamping out diphtheria and other diseases, which took off more people than cholera was likely ever to do. The speaker alluded in this connection to the necessity for more Willard Parker hospitals.

Dr. Janeway sent a note, and said that disinfection of the discharges and sanitary suggestions already made impressed him as very important.

The Chairman, Dr. Chapin, thought the steamship companies were negligent in not having more than one ship surgeon to look after the many passengers, and check diarrhœa in its commencement.

Dr. Gihon, of the Navy, was asked to speak, and said that while the health officer of this port was not to blame, the passengers, sick and well, ought to have been taken off the vessel immediately on its arrival. If necessary, they might have been transferred to another vessel, and steamship companies should keep one for this purpose. Then the ship should be thoroughly cleansed and disinfected, which was a great work. The speaker thought few people knew what thorough cleansing of a house was. The undertaking was so great that he recommended they commence at the dirtiest part, the cellar, lest they get tired and stop at the second floor instead of at the attic. The greatest danger in New York and Brooklyn was in the cellars.

Dr. Donovan showed specimens under the microscope and cultures from the cases which had occurred in the city.

The Paris Academy of Medicine wants a better home, and has asked the government to give it the old Mont de Piété, in the rue Bonaparte, near the School of Fine Arts.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 23, 1892.

H. P. Loomis, M.D., President, in the Chair.

Cystic Lesions of the Ovary and Tube.—Dr. George C. Freeborn presented a large number of specimens illustrating cystic lesions of the ovary and tube. The first series of four specimens were examples of pedunculated cysts of the Fallopian tube, the so-called hydatids of Morgagni. These cysts were quite common, and the pedicles varied considerably in length, those shown in the specimens being mostly of the short variety. The next series consisted of seven specimens of hydrosalpinx, showing the arrangement of the cysts and their appearance at various stages. Then came three specimens of parovarian cysts, and following these, twelve specimens showing the small follicular cysts found in cases of chronic ovaritis, and six specimens of small retention-cysts of the ovary. The next series consisted of six specimens of what are called unilocular cysts of the ovary, in which the ovary is almost entirely converted into a good-sized cyst, so that scarcely any ovarian tissue can be found on microscopical examination. Then followed twelve specimens of multilocular cysts, and three of dermoid cysts. One of the latter was a rare specimen, as the whole cyst-wall was calcified. Three papillary cysts were also shown.

Dr. Freeborn called attention to the method which he employed in preparing these cysts, a method which he had described about three years ago. While in the fresh state, any rent in the cyst is carefully sewed up and a cannula tied in, and then the cyst is distended under a pressure of twelve to eighteen inches with Fleming's mixture of chromic and acetic acids. The distended cyst is then immersed in a large quantity of the same fluid for forty-eight hours, when it will usually be found that the cyst-wall has become sufficiently firm to preserve the shape of the cyst. This method of preparation is a great aid in studying the configuration of the surface, and the various attachments of a cyst.

Œdema and Inflammation of the Umbilical Cord.—Dr. R. G. Freeman presented an umbilical cord which was œdematous, and presented evidence of a localized inflammation about two of the vessels. Labor had come on three weeks before full term, and a fœtus of fair size was born dead. The placenta appeared to be normal. The umbilical cord was thinned out at the umbilicus, and was dilated in the middle to three centimetres in diameter. Microscopical examination showed an extensive collection of small round cells surrounding the vein, and a small collection around one artery. Most of these cells were in the jelly of Wharton. The condition of the cord, together with the fact that the child was dead before term, indicated a possible tubercular taint, but Dr. Bird, who had delivered the child, was unable to find any evidence of tuberculosis in the family, and there was no definite history of syphilis. Out of one hundred consecutive cases examined in the Sloane Maternity Hospital, only three presented an œdematous condition of the cord, and in these there was not so much œdema as in this specimen, and there was no infiltration of small round cells.

Dr. Freeman also showed the remains of the allantois in the cord.

Repeated Attacks of Dysentery and Hepatic Abscess.—Dr. G. M. Edebohls presented a specimen from a patient who had had repeated attacks of colitis during a period of six years, each attack being followed by an hepatic abscess, and each abscess being cured by operation, until, finally, the patient succumbed to the sixth abscess. The patient was a man forty-three years of age, who was perfectly well up to the summer of 1885. At this time, he had a violent attack of dysentery, from which he recovered, but slowly. He remained in fairly good health up to May, 1886, when he experienced pain in the epigastrium. When first seen by the speaker in August, 1886, this region was the seat of a tumor, five inches in diameter which, when punctured with an exploring needle, yielded pus. On August 31, 1886, an abscess of the right lobe of the liver was opened under cocaine anæsthesia, and ninety grammes of pus evacuated. Adhesions had formed between the liver and the parietal peritoneum. The abscess-cavity was irrigated and drained, and after three weeks the tubes were removed and the cavity quickly healed. He remained well until December of the same year, when a second abscess appeared, about five centimetres to the right of the former one. The diagnosis was again confirmed by puncture, and the second operation was performed under ether anæsthesia. This abscess was found in the liver substance at a depth of three centimetres, and contained eighty grammes of pus. After draining for three weeks, the wound closed, and the patient again enjoyed good health for four years, with the exception of occasional slight attacks of diarrhœa. In August, 1890, he had another severe attack of dysentery, and two or three weeks later began to suffer from pains over the right lobe of the liver, associated with chills and an elevation of temperature, as high as 103° F. The patient was etherized and an incision made into the abscess, which was found in the ninth intercostal space and eight centimetres below the skin level. As the tumor this time was not so prominent as on the previous occasions, the speaker said he was somewhat fearful that there would be no adhesions found, and had accordingly made preparations for a careful laparotomy, should this be required. It was fortunate that he did so, for after cutting through the abdominal walls, he found himself in the general peritoneal cavity. Exploring with the finger, he found that all the organs in the vicinity were normal, except for the bulging of the right lobe of the liver. The cicatrices of the former incisions were found, and it was ascertained that the peritoneum directly behind was again free, the adhesions having been absorbed, and their place occupied by normal peritoneum. The surface of the liver was sutured to the parietal peritoneum, and packed with iodoform gauze, and at the end of a week, adhesions having formed, the liver was incised, and a much larger quantity of pus evacuated than at either of the two previous operations. As the symptoms of sepsis continued after this operation, the presence of another abscess was suspected, and, as there was some pain on pressure in the eighth intercostal space on the right side posteriorly, a needle was inserted at this point, and another abscess found. This one was opened from behind in the eighth intercostal space. On reaching the pleura, the pleura, diaphragm, parietal peritoneum, and liver were successively perforated with a Paquelin cautery, and over one pint of pus evacuated. By introducing a pair of uterine dressing forceps into this abscess-cavity, and the finger into the anterior wound, it was ascertained that there was only one inch of normal liver substance intervening. This was perforated with the forceps, and thorough drainage established. Thinking that some of the abscesses might have been due to the retention of certain substances, it was thought best to keep the cavity open for some time, and to irrigate it daily.

On January 26, 1891, about three months after the operation, the drainage-tube was removed, and the wound allowed to close. On April 1, 1891, after another attack of acute colitis, another abscess appeared in the left lobe of the liver, and an incision under cocaine anæsthesia evacuated 80 grammes of pus. This abscess was situated at some distance from the surface of the liver, and adhesions had formed, so that no difficulty was experienced in the operation. The patient recovered, and remained well up to March 1, 1892, when he had another severe attack of dysentery, which was followed in two weeks by pain over the right lobe of the liver, and evidence of another abscess. This abscess opened spontaneously beneath the ribs, so that it was only necessary to insert a drainage-tube, and irrigate the cavity. The prolonged entero-colitis had, however, left the patient in a

very feeble condition, so that death from exhaustion occurred on March 23d.

The specimen, which had just been removed, showed about one-half of the large intestine, which was the seat of the characteristic lesion of dysentery. The liver showed the fresh abscess-cavity and also the cicatrices indicating where the other abscesses had completely healed. The kidneys were enlarged, and apparently the seat of fatty degeneration.

Each of these attacks of hepatic abscess, Dr. Edebohls said, was preceded by a typical attack of acute colitis, and the pus evacuated at each operation was examined carefully, as was also the subsequent discharges, for echinococci hooklets, but none was found. Unfortunately, no examination had yet been made for the amœba coli, but some of the pus from the last abscess would be subjected to examination for this organism. The case was one of considerable interest, for hepatic abscess is always looked upon as a serious affection, and yet here five operations were successfully performed for this condition, and the patient only succumbed to the sixth abscess, which opened spontaneously. It was also interesting to note that there had been no diminution in the bulk of the liver, notwithstanding the large quantities of pus which had been evacuated at various times.

Dr. J. S. Ely said that the absence of any diminution in the size of the liver was extremely interesting, in view of some recently published experiments made upon animals by Ponfick, who found that considerable portions of the liver could be removed, and yet after a given time, when the animals were examined, it was found that a very considerable new formation of liver-tissue had taken place.

Gun-shot Wound of the Brain.—Dr. J. S. Thacher presented a brain as an illustration of how one bullet might cause two wounds. The specimen had been removed from a patient in the hospital service of Dr. McCosh. The man lived eight days after the injury. The bystanders who saw the shooting said that only one shot was fired, there was only one empty chamber in the revolver, only one hole in the skull, and only one bullet was found. Although there was only a single external wound, situated just above the bridge of the nose, there were two openings through the dura mater, one on each side of the falx, and two cavities, situated symmetrically, one in each frontal lobe, about one inch in transverse diameter, and having softened walls. They extended up to the tip of the anterior horn of the lateral ventricle on each side, and contained clotted blood. The bullet was found just inside of the inner plate of the skull. One of the holes may have been made by a splinter of bone.

A Very Rare Malformation of the Bladder.—Dr. Ely presented a specimen which was removed from a man who had presented no bladder symptoms during life. At the autopsy, in cutting through the abdominal wall, the knife cut through the fundus of the bladder, which was found to extend up to within one inch of the umbilicus. The bladder was long and slender, and its walls were of normal thickness, and not at all diseased. This malformation of the bladder appeared to be due to a persistence of the urachus. A review of the literature of the subject shows that this malformation is extremely rare. Luschkur described a persistence of the epithelial structure of the urachus, and cysts of the persistent urachus sometimes occur, but he could find no case on record in which the bladder extended upward in this peculiar manner.

Dr. Ely also exhibited the bladder of a child at birth, showing how, when distended, it extended up to the umbilicus, and how very short the urachus is at this time.

Rupture of the Kidney During Parturition.—Dr. J. C. Smith presented kidneys which had been removed from a child on the day previous. One of these showed a rupture which he believed had occurred during labor. The labor was a difficult one, the child presented by the vertex, and was delivered by the forceps, much difficulty being experienced in the delivery of the hips. The obstruction to delivery was due to a projection forward of the coccyx. The autopsy showed a large extravasation of blood around the kidney behind the perineum, with a little bloody serum and coagulated lymph in the peritoneal cavity, and a beginning peritonitis. The child died with symptoms of meningitis, but there was no evidence of this at the autopsy.

The Growth of Voluminous Cultures of the Tubercle Bacillus.—Dr. T. M. Prudden said that in his published account of the technique of making tuberculin Koch describes the method as consisting in floating little scales of the cultures of the tubercle bacillus on fluid culture media. This is not a new method, as it has been employed by the French for some time, and in this country it has been used for over a year by Trudeau. The tubercle bacilli grow voluminously if floated upon an appropriate fluid medium, but the growth is very scanty if the pellicle so formed is allowed to sink to the bottom. He had found that this difficulty could be obviated by introducing sufficient cotton, sterilized by heat, into the vessel to allow of the scales of the tubercle bacillus resting on the fibres of the cotton.

Extensive Valvular Disease of the Heart.—Dr George P. Biggs presented a specimen of the above. It was removed from a girl, thirteen years of age, who had had two attacks of rheumatism, and had complained for some time of marked dyspnœa on slight exertion, and of considerable cough. At the time of her admission to the hospital there was moderate general anasarca, the cardiac area was decidedly increased, and the apex beat was in the sixth space, four inches to the left of the median line. A presystolic and a systolic murmur were heard just above the apex, the latter being transmitted to the left. At the second intercostal space to the right of the sternum, a systolic murmur was heard, which was transmitted to the neck, and a diastolic murmur, which was transmitted downward and to the left. The area of the liver was considerably enlarged. At the autopsy the heart was found to be about the size of a fully developed adult heart, and gave evidence both of hypertrophy and dilatation. The aortic valve showed thickening and retraction, the mitral valve showed very marked stenosis, and the tricuspid valve showed a moderate but distinctly appreciable narrowing of its surface. The pulmonary valves were normal. The only other lesions were those due to chronic congestion of the various organs.

Dilatation and Extensive Atheroma of the Aorta.—Dr George P. Biggs also presented a heart which had been removed from an adult, forty-four years of age, in whom death had resulted from a pericarditis and a pleurisy following a septic condition connected with disease of the urinary passages. The aorta showed very extensive atheroma throughout its whole extent, with calcareous deposits in places, and at its origin, just above the valve, there was a distinct dilatation, five centimetres in diameter, with calcification of its walls. The valves were normal, except a marked thickening of the bodies in the centre, which apparently compensated for the relaxation of the valve at the base. There was no deposit of fibrin.

A Cyst Growing from the Hilum of the Spleen.—The President presented the specimen. The patient from whom the specimen was obtained was a woman, forty-six years of age, who died after an eight months' illness from cancer of the liver. The condition of the spleen was not suspected during life. Closely adherent to and apparently growing from the hilum of the spleen was a single large cyst, about five inches in diameter, and containing twenty ounces of a whitish, amber-colored, and slightly viscid fluid, rich in albumin. The wall of the cyst was an eighth of an inch in thickness, and from its inner surface projected several smaller cysts about the size of walnuts. These latter contained a brownish fluid, and microscopical examination showed the fluid contained cylindrical epithelial cells, fatty corpuscles, Drysdale cells, red blood-corpuscles, and granular material. The interior of the

wall of all the cysts was comparatively smooth and lined with cylindrical epithelium. In appearance, structure, and the character of the contents this cyst resembles an ovarian cyst.

Dr. Freeborn considered the specimen to be an ovarian cyst. It was probable that there had been some peritoneal inflammation and contraction by which the cyst had been lifted out of the pelvic cavity, and then adhesions had formed between the cyst and the spleen.

The Society then went into executive session.

OUR LONDON LETTER.

(From Our Special Correspondent).

CHOLERA — BRITISH PREVENTIVE MEASURES — CHOLERA AND LITIGATION WITH SEAMEN— THE FIVE YEARS' CURRICULUM FOR STUDENTS—DEATH OF SIR GEORGE MACLEOD—THE HEALTH OF SIR RICHARD OWEN.

London, September 10, 1892.

Cholera is still the question of the hour, although the popular alarm caused by its first appearance on our shores has now largely subsided. Twenty-four cases of undoubted cholera have occurred since August 25th, and of these nine have proved fatal. There have been three cases, with one death, in London. Everyone of these twenty-four cases was introduced from the Continent, and so far there are no reasonable grounds on which to expect that the disease will become epidemic among us, as in 1866. In that year sixteen thousand persons were attacked, but the outbreak was limited to an area of East London supplied by the East London Waterworks Company, and a careful investigation showed conclusively that the area in question had been supplied with unfiltered water which had become contaminated with choleraic discharges. The lessons of that epidemic have not been lost, and never have our sanitary arrangements been in a more perfect state for warding off a threatened outbreak than at the present moment. Water-supplies and drainage have been looked to, and sanitary inspectors have been active in condemning all meat, fruit, or vegetables deemed unfit for consumption as food. Prompt arrangements have been made for isolating any cases that may occur, and many of the hospitals and infirmaries have set aside beds for cholera patients. The clothing of all infected persons is to be destroyed at once, and choleraic discharges either disinfected or burnt. These measures have been carried out in those cases which have already occurred. An important step has been taken, with regard to the immigration of destitute aliens, which cannot fail to have a great influence in checking the introduction of cholera into this country through such agencies. Hitherto the authorities have had power, in the case of a ship arriving with cholera on board, to take the names of such passengers with the addresses to which they are proceeding, so that they can, if necessary, be kept under sanitary supervision. An order has been issued by the Local Government Board, extending these regulations (at the discretion of port medical officers) to all ships, whether infected with cholera or not.

At the present moment I believe that there is no case of cholera in Great Britain. The chief Medical Officer of the Local Government Board (Dr. Thorne Thorne) made a statement to that effect yesterday, and no intelligence of any fresh cases has since been received. Comparing the small mortality here with the ravages caused by the disease abroad, there does not seem any cause for great alarm here. Even if we add to the cases of undoubted cholera (24) those of choleraic diarrhœa (25), we only get a total of forty-nine cases. The outbreak on the Continent is already on the wane since the advent of cooler weather, and it is possible that by the time these lines appear in your pages all cause for apprehension may have disappeared.

Cholera has been the occasion of at least one case in the law courts. The crew of a Liverpool ship were charged before the magistrates at Falmouth yesterday with refusing to proceed with their vessel to Hamburg. They had refused on account of the prevalence of cholera at the latter port. It was stated on behalf of the owners that there would be no risk of infection, as it was proposed not to land the men at Hamburg, but to transfer them to other steamers at Cuxhaven which would bring them home. The defendants' solicitor, however, said that if the men were discharged at Cuxhaven, the vessels which would bring them back to this country would have come from Hamburg, and would carry in the tanks and bilges the infected or contaminated water of that city, as well as vegetables and other provisions, which might also be sources of contamination. He hoped, therefore, that the Bench would hold that the crew had reasonable cause for their refusal to carry out their articles. The case was adjourned till evening in order that additional information might be obtained. On the resumption of the proceedings several telegrams were read, and in one of these it was stated that Cuxhaven was not infected, but that cases of cholera had occurred there. The magistrates decided to dismiss the case, and the nineteen seamen were discharged.

Commencing with the coming winter session, the medical curriculum will in future be one of five years. Nominally, indeed, the new regulation came into force at the beginning of the present year. Most students, however, enter in October, and the dividing line may therefore be fairly drawn now between students under the old and new regulations, respectively. A certain amount of elasticity is allowed as to the way in which the fifth year is to be spent by the student. Half of it may be spent otherwise than at a medical school, *e.g.*, at a special hospital or workhouse infirmary. No detailed arrangements have yet been made as to the subjects to be taught in the medical schools during the fifth year. A course on mental diseases is proposed at University College, and both at Charing Cross and Westminster Hospitals; at the two latter institutions ophthalmology will also form a subject of instruction during the same period. At St. Mary's Hospital diseases of children, fevers, hygiene, and psychological medicine are to be studied during the fifth year. No announcements have been made as to the instruction which will be given at the other metropolitan medical schools during the final year, but it may be surmised that clinical teaching will occupy an important place.

Sir George Macleod, of Glasgow, died suddenly last week, aged sixty-five. He was a son of the well-known Scotch divine, the late Rev. Norman Macleod. Sir George Macleod had a distinguished career as a surgeon. He acquired a large experience of military surgery in the Crimean War, where he was surgeon to the general hospital in the camp before Sebastopol, and became senior surgeon to the civil hospital at Symrna. On his return to Glasgow he became surgeon to the Royal Infirmary, and subsequently surgeon to, and lecturer on clinical surgery at, the Western Infirmary. At the time of his death he was Regius Professor of Surgery at the University of Glasgow, Surgeon to the Queen in Scotland, and Crown Member for Scotland of the General Medical Council. He was knighted five years ago. He was the author of several contributions to surgical literature.

The eminent anatomist, Sir Richard Owen, is much better in health, and there are now fair hopes of his recovering from his recent severe attack of stomatitis, in spite of his advanced age—eighty eight.

First Class in Geography.—A London physician, writing in *The Lancet*, said that he had been offered some land in South America in payment of a charge for medical attendance, and on consideration had decided to accept it, and thus become "a landed proprietor in the United States!"

HOW SHALL WE TREAT CHOLERA?

To the Editor of the Medical Record.

Sir: In view of the imminent danger of an outbreak of cholera in our community, the disease having been officially declared to be present in this city, I deem it timely to offer to your readers some suggestions for the treatment of this dread disease.

From what personal knowledge has been derived from the daily press, I would infer that the management of cases of cholera in the quarantine hospitals of this port has been mainly expectant, that is to say, limited to enteroclysis of Cantani, with hot solutions of salt and bicarbonate of soda, with the addition of tannin, and the use of stimulants. This method will no doubt have its followers, and in a certain number of cases prove successful, but it is difficult of employment in a tenement-house practice, where the majority of cases is likely to occur.

Therefore I wish to call attention to a very simple and rational method of treatment, one that can be employed promptly and requires little loss of time to a busy practitioner. In the July number of the London *Practitioner* for 1875, Surgeon A. R. Hall, of the British army, who had a large experience in the treatment of cholera in India, publishes his views on the treatment of this disease, accompanied with communications from a Mr. Higginson, civil surgeon of Kheir, in Oudh, indorsing the success of his method.

The method of Hall is the use of a ten per cent. solution of chloral hydrate, giving from ten to twenty drops hypodermatically at a time, according to age and severity. The injection is repeated in from a half to two hours, and again later if found necessary, according to the condition of the case. The strength of the solution is such as to avoid suppuration or sloughing, and is so graduated that every ten drops represents one grain of chloral.

The method is based upon the pathological condition produced by the cholera poison, viz., an irritation of the vaso-motor centres, causing excessive contraction of every artery and arteriole in the body, together with the muscular structure of the heart. This view easily explains all of the symptoms of collapse, and rationally demands the administration of a sedative to the sympathetic nervous system. As vomiting excludes the administration of any remedy by the mouth, the hypodermatic method is the most successful.

The results, as given by Mr. Higginson in seventeen cases treated by this method, are highly encouraging, only two deaths occurring, one of these being due to negligence on the part of the native physician, who was afraid to give sufficient chloral to secure reaction from the collapse.

Certainly this is a splendid showing for the treatment, when we consider the severity of the disease as it occurs in India, and know of its great mortality. I therefore think we should feel encouraged to employ it, rather than depend upon opium or morphine or any of the antiseptic remedies, except in the premonitory diarrhœa. For the premonitory diarrhœa occurring during the prevalence of cholera I should prefer the use of naphthalin in five-grain doses, repeated every two or three hours, as it is the only antiseptic that does not undergo decomposition in the entire length of the alimentary canal. Moreover, it is harmless, as it is not absorbed. The same cannot be said of salol, which darkens the urine considerably. The hypodermic employment of a solution of common salt, one drachm to the pint, after the manner suggested by Professor Osler in his recent work on "Practice of Medicine," would be preferable to enteroclysis in desperate cases of collapse, but if any one of your readers will refer to the article of Hall I have mentioned, they will scarcely regard as necessary any measures further than the use of hypodermic injections of chloral hydrate.

THE TREATMENT OF CHOLERA BY RECTAL INJECTION.

To the Editor of the Medical Record.

Sir: With cholera in our port and in our city, and also in many parts of our country, it is the duty of every physician who has had any practical experience in the treatment of this hidden pest to speak out and tell what he knows about the treatment, and what has been his success. In the epidemic of 1849, in this country, the older physicians turned over their cholera patients to the young practitioners, and gave them little or no advice about the treatment. We were thus thrown upon our own resources, and did the best we could. We could find no pathology in the medical books, and no reliable remedies. But we very soon learned the symptoms. There was purging of watery stools without any pain and without any fecal odor. The patient would pay no attention to his diarrhœa, until he began to vomit. Then he would send for the doctor, who would usually prescribe opium, camphor, bismuth, etc. He would also order mustard plasters over the stomach and bowels; but the purging and vomiting would continue, cramps in the extremities would set in, and collapse would soon follow. The body now became cold and purple, the voice husky, often reduced to a whisper, the purging and vomiting still continued, and in a short time the scene was over.

Now and then a vigorous patient would rally, and reaction come on, especially when the dejections had not been copious, and not frequent. The treatment was entirely empirical, and when the epidemic was over physicians were quite as unsatisfied and unsettled about the treatment of cholera as they were before it came.

The epidemic of 1854 was not as severe as in 1849—at least the mortality was not so great. The Board of Health in Williamsburg, then a corporate city, opened a cholera hospital July 30th, and placed it under my charge. During August and September thirty-six patients were admitted, and most of them in an advanced stage. Many were of intemperate habits and broken constitutions, and few recovered. Two men were brought in with congestion of the brain from frequent doses of opium, and were both in collapse, and both died. One woman was received in an advanced stage, with a babe aged ten days. Both died. Another woman was convalescing from cholera, but died of uterine hemorrhage from miscarriage. From this class of patients it will be readily inferred that most of them died, and such is the fact. Only fifteen out of the thirty-six recovered. The treatment at first was opium and astringents to check the stools, and stimulants to keep up the strength. Unfortunately all remedies were vomited as soon as they were taken. I at once began medication by the rectum, and ordered astringents to be thrown into the bowel after each stool, but the purging and vomiting continued. Stimulants were combined with astringents, and the stools were not quite so frequent. Brandy and strong tea were then used, and sometimes brandy and coffee, and encouraging results followed. At last coffee and brandy injections were used exclusively, and four to five injections would usually control the purging and vomiting also, and the patient would show signs of recovery. The pulse became stronger, the body would become warm, the husky voice was more natural, and the cramps in the extremities were less distressing; the patient would fall into a stupor for a few minutes, and then cry out with cramps. He would roll about the bed, and be liable to have another stool, when another injection would be given, and this would probably be the last one necessary. After an hour or so a little hot tea or coffee would be given the thirsty sufferer, and repeated frequently if there was no disposition to vomit. Later he was allowed to hold ice in his mouth, but he would crush the ice with his teeth, for he was too thirsty to wait for it to melt. In six or eight hours the patient would be likely to have a small stool of more consistence and some fecal odor. If there should be no stool in twelve or fourteen hours

pill of calomel and camphor would be given, with a desire to produce a fecal stool. Strained beef-tea was now given cautiously, and with no relapse the patient would recover.

Of the fifteen patients saved in the hospital at least ten recovered after the brandy injections were decided upon. Indeed, this treatment saved nearly every patient after it was fully adopted and strictly carried out.

The two nurses in the hospital, husband and wife, had learned when and how to give the injections. Patients would be brought in at midnight, purging and vomiting, and both would be under control before morning. It was considered necessary to dilute the brandy, to prevent any inflammation of the mucous membrane, and coffee was chosen, as it was considered a powerful nerve stimulant. An ounce of brandy with two ounces of coffee constituted the injection, as a rule. This was thrown into the rectum with an old-fashioned metal syringe, and followed promptly after each stool. For a strong and robust person the brandy was increased. If the patient had lost a great deal of fluid, no time should be lost in giving the injections. This loss of fluid from the intestinal canal must stop of itself, or must be checked, or the patient must die. This is perhaps putting it more plain than professional, nevertheless it is true.

In the epidemic of 1866 there were not enough cases of cholera in New York to give the treatment by injection a thorough trial. Dr. Dalton, Sanitary Superintendent, had heard something about brandy injections, and recommended his sanitary doctors to try the treatment. But they began the treatment too late, and after the old routine treatment had failed, the young doctors were directed to begin the treatment of cholera with "a mixture of laudanum, spirits of camphor, and chloroform. But if the patients cannot retain the medicines in the stomach, then a mixture of brandy and strong tea is to be injected into the bowels until the discharges have ceased." If the doctor had any faith in brandy injections (and he appears to have had a little), why did he not instruct his young physicians to begin the treatment by injections at once? The first symptom of cholera is one or more liquid stools; and this is the first symptom that demands the doctor's attention. If the stools are checked at once, there may be no vomiting, and very little cholera in that particular case. There is no great prostration until there has been a considerable loss of fluid. The physician who checks the cholera-stools early and keeps them under control, takes courage at once, and so does his patient.

Dr. Alonzo Clark taught his class that cholera depended upon paralysis of that portion of the ganglionic nervous system that presided over the alimentary canal. Certainly we know that gallons of fluids escape from the body through the intestinal canal, and they escape with alarming rapidity, and vomiting must check them or there is no hope of recovery.

Now a word to the doctor to simplify his treatment. First, he must arm himself with a six-ounce syringe, a bottle of good brandy, the older the better, and a bottle of black coffee, to start with. When he reaches his patient, he should give him an injection of brandy and coffee, even before he looks at his tongue, or feels his pulse. Then he will examine his patient, and find out what is the matter. If it should prove to be a simple case of diarrhœa, the injection will do no harm. If it should be cholera, a very important step has been taken in the treatment of the case.

Now look at the stools, or the fluid that has been vomited, and see what they contain. If they are characteristic of cholera, have another injection ready the moment he has another stool, while the bowel is empty, and throw the injection into the bowel at once. If the patient should be unable to retain the injection, press a napkin against the anus for a few minutes, mustard over the stomach and bowels, keep patient in bed and as quiet as possible. Repeat the injections until the passages are controlled; when this condition is reached there is no haste about further medication. Flannels should cover the body, and friction may be applied to the limbs to allay cramps. Hypodermic injection of morphine may be given, if the cramps are very severe.

Later treatment must depend upon the condition and symptoms of the patient.

Truly yours,

O. H. Smith, M.D.

New York, September 17, 1892.

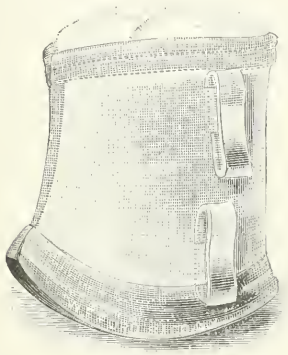
New Instruments.

AN APPLIANCE FOR ADMINISTRATION OF ETHER.

By W. K. Rogers, Jr., M.D.,

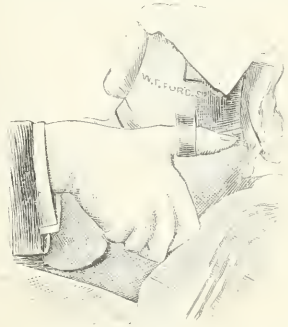
new york.

Strictly speaking, the contrivance is not original, being an aggregation of good points of existing devices. It is made of flexible rubber, to fold flat, and resembles the



gauntlet of a glove, with loops for thumbs, to facilitate holding in place, is convenient to carry, easy to clean, disinfect, and refit, adaptable to face of adult or child, admits of free use of hands for controlling jaw and tongue, wastes very little ether, and induces rapid narcosis.

One square yard of absorbent gauze is folded into a strip, the width of the cone. The strip is then laid in plaits like an accordion, as nearly as possible an inch and a half wide, a short end lapped over the bundle of plaits,



which is to be wadded tightly into opposite end of cone from that applied to face—*i.e.*, into small end if adult, large end if child—the covered side of gauze even with top of cone.

On removing gauze, turn the cone inside out, scrub, and soak in bichloride.

A wet towel placed over the cone during use, will save

a good deal of needless evaporation of ether, without interfering with respiration.

Our statistics at St. Luke's Hospital, for which indebtedness is due largely to Dr. Dade and Dr. Brouner, of the House Staff, show that this device uses an average of two and three-quarter ounces of ether an hour; three to five minutes being the average time for producing narcosis.

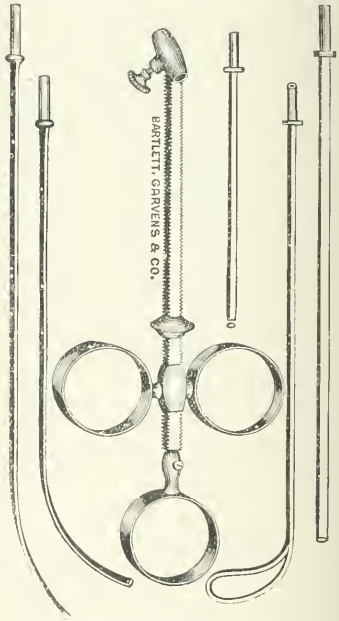
One cut represents the cone as made by the W. F. Ford Surgical Instrument Co., the other, cone and position of hands in drawing the jaw forward. The lower angle of cone should rest on the chin, not over it.

A MODIFIED HARTMANN SNARE—SOME REMARKS UPON ITS USE.

By JOHN DUNN, M.D.,

RICHMOND, VA.

The snare, of which there are cuts accompanying these remarks, seems to me to have certain advantages over any with which I am acquainted. The cannula for the nose and faucial tonsils is not a cylinder, as is the case with Bosworth's, Jarvis's and others, but is made perfectly flat its whole length, so that it resembles somewhat a very narrow knife-blade; its width is 3 mm., its antero-posterior diameter is only $\frac{3}{4}$ mm., so that the opening at the end is just large enough to admit easily a No. 3 piano wire. Furthermore, the far end of the cannula has a knife edge. It is to this flattening of the cannula, blade and tip, that is to be attributed its chief excellence over other forms of cannula. Where the cannula is cylindrical there is more or less tendency, after threading it, for the wire-loop to revolve as it strikes against the various projections in the nose; and this makes it more difficult than necessary to adjust with desired accuracy over the part to be removed. In the flattened cannula this tendency of the wire to revolve is done away with. Again, in the round cannula the loop enters the tube in its mid-plane, leaving the distance of half the diameter of the tube behind the wire where it enters the tube. This makes an unnecessary difficulty in removing growths to their very base. In the Jarvis snare that I have the diameter of the tube is 3 mm., a diameter so great as to have caused me to discard this, in many respects, excellent instrument. In the flattened cannula, whose antero-posterior diameter is less than 1 mm., the end of the cannula can be forced even into the origin of growths or hypertrophies. So exactly can this be done that this form of cannula can be used for snaring single granulations of the pharynx. Again, the flattening of the cannula allows it to be carried where the round cannula will not go, and thus at times individual small polypi can be removed at their origin with it, when with the usual round cannula we have to be satisfied with removal of a part of these growths. Of especial value is this flattened form of the cannula for the removal of hypertrophy of the posterior end of the inferior turbinate. Here the cannula lies flush against the inferior turbinate its whole length, and with the steel wire slightly bent the removal of this hypertrophy becomes one of simplest operations done in the whole range of nasal surgery; so that, when White's palate retractor is in place—and as the use of this instrument allows the operator to see perfectly the part to be snared it should always be used in these cases—it is rarely necessary to make more than one attempt for the removal of this hypertrophy. In the operations for deflected septum or the removal of spurs of the septum after the use of the saw it often happens that there remain shreds of connective tissue, or particles of the spur, or even, at times, when we have sawn through the spur, it remains attached by a part of the mucous membrane which evades all our attempts to reach it with the saw—in all of these cases the flattened cannula allows an accuracy in the removal of these difficulties which cannot be obtained with the round cannula. In the case of anterior hypertrophies, and of those hypertrophies which make their appearance along the under side of the inferior turbinate, so that this turbinate is always touching the floor of the nose, where removal is deemed the best treatment, by using the flattened cannula the transfixion needles can be done away with. In regard to the use of the snare for the removal of tonsils, I consider it, of all methods, the best, so that for nearly three years now I have used no other where the patient would submit to having the "tonsils cut out." Where the patients have preferred it, of course, the cautery has been used; my advice has been, though, to have the tonsils removed with snare, and for more than a year I have not used the cautery for this purpose. The snare has many advantages over the guillotine. One snare does for all cases. The bleeding and pain are in every case less; in most cases, after the application of cocaine, so trivial as to amount to nothing. It can be used in those cases where the tonsils are developed so far down the throat that no guillotine as yet constructed could reach them. In those cases where the tonsils have become adherent to the pillars of the fauces, with the proper assistance of a small bistoury a snare can be used



with much satisfaction. The snare can be worked as rapidly, or even more rapidly, than the guillotine, and those efforts at gagging, caused in many cases by the endeavor to force the guillotine into place, are not necessary where the snare is used. On one occasion, in a young lady sixteen years of age, I removed with the snare, at one sitting, both tonsils to the roots, when they were sufficiently swollen to meet across the pharynx and to have exudation coming from the follicles. This case healed beautifully without further treatment. The bleeding at the time of the operation amounted to nothing.

The cannula next the handle to the left in the cut above is to be used for the removal of post-nasal adenoids and other such work in the post-nasal space as can be done most advantageously through the mouth. It is, also, like the straight cannula, flattened, so as to lie if necessary close against the post-pharyngeal wall; the free end is broader than is the case with the straight cannula, so as to allow the formation of a broader and more circular loop close to the end of the cannula. The cannula next

straight cannula in the above cut is in the form of post-nasal guillotine. The guillotine has a groove in into which presses the wire, which in turn is kept in ace partly by the shoulder of this groove and partly by e resiliency natural to the well-made piano-wire. The e of this instrument is suggested by its appearance. It to be passed into the naso-pharynx, and pressed firmly ainst the posterior wall, after which the wire is drawn rough the cannula, cutting through all the tissues con-ned in the guillotine. There are certain developments the third tonsil where this guillotine can be used ad-ntageously and to the saving of much time. These illotine cannulas are of two sizes. The back edge of is guillotine is sharp, so that it can be used as a curette those cases where snaring is impossible. The left hand ure in the cut is the cannula to be used in snaring the lenoid tissue from the base of tongue. The patient is re made to pull the tongue forward, as in operations in e larynx, when with the aid of a laryngoscopic mirror is hypertrophied tissue can be seen, and, by pressing the it cannula firmly against the tongue, can be snared in ch quantities as may be deemed advisable. I have und this to be the most satisfactory method of reducing is tissue where true hypertrophy of it exists.

The small cannula is for use in the ear, and the instru-ent makers are to be complimented upon the delicacy f its construction. The handle is after the German odel, and has advantages over any other handle I have en. The ring on the end of the handle revolves, so that ie handle can be used in any position. The cannulas into a tube placed at an angle of forty-five degrees to ie handle, so that the light from the forehead mirror is ot interfered with by the hand manipulating the instru-ient. The snare is tightened by pulling with the index-id middle-finger in the rings of the finger-piece at the de of the bar. This finger-piece is very strongly made, nd slides up and down a bar which is cogged. There eed be no cogs anteriorly and posteriosly, so as to allow ie finger-piece to slide easily along the bar. The handle provided with a rider, so that the snare can be used for ow as well as rapid work. This snare can thus be made draw either with the screw motion or by straight press-re. The handle and cannula are, of course, detach-ble, the cannulas fit into the tube at the end of the andle and are held in place by a small screw placed be-eath the handle at this point. A laryngeal snare, for se in those cases where a laryngeal snare can be of ervice, is also flat and has the curve of one of the rench laryngeal forceps. The differences between this nare and the Hartmann are slight, and consist chiefly n changes of the proportions of the cannulas, which are engthened and flattened their whole length; in the pro-luction of a more delicate cannula, with especial reference o preventing any slipping of the noose when once formed, nd in the addition of a curette to the guillotine, whose proportions are different from that in the Hartmann case. No claims are here made for originality, and yet, I think, he modifications will be found to greatly enhance the alue of the Hartmann snare. The snare was made for ne by Messrs. Bartlett, Garvens & Co., of Richmond, Va.

Small-pox and Anti-vaccination.—A cable despatch says that an epidemic of small-pox has broken out in the town of Leicester, and that English sanitarians are watching its progress with considerable interest. The people of the town have for years strongly resisted every effort to enforce the law requiring the vaccination of children, and the Government concluded to leave the people alone. Small-pox had not invaded Leicester until very recently. Physicians and others interested in sanitation have expressed the opinion that, if it ever gained a foothold it would ravage the town, and now their prophecy is in course of fulfilment.

The Birth-rate in London, taking the average of the past ten years, is 2,866 per week.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 17, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	58	9
Scarlet fever	44	5
Cerebro-spinal meningitis	1	0
Measles	37	2
Diphtheria	79	18
Small-pox	6	2

Varicella	0	0.
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Original Keratosis.—A curious Jewish tradition reports that Adam was entirely clothed in a hard, horny skin, and only lost it and became a subject to evil spirits on losing Paradise. The nails are the remnants of this dress, and whoever cuts them off and throws them away does himself an injury. An old Persian chronicle says that Eve also possessed this dress, and the nails were left to remind them of Paradise.

Straightening the Eyes of the Japanese.—"I was recently in Japan," says an American, "and I met there several American and German doctors who were getting rich by straightening the slant in the Japanese eye to make it look like the beloved Caucasian's optic. The Japanese, you know, show the traces of their Mongolian origin more plainly in the shape of their eyelids than in the color of their skin, and those who can afford it are ridding themselves of this unmistakable evidence of their despised ancestry by submitting to a simple and comparatively painless operation, which consists in the surgeon slitting the outer rim of the eyelids in a straight line for the barest infinitesimal part of an inch. The wound is then covered with a thin piece of chemically prepared sticking-plaster, the faithful subject of the Mikado goes on about his business as if nothing had happened, and in a few days the wound is healed and he looks on his envious fellows through lids as straight as the American's."—*Medical Times.*

A Palatable Castor-oil may be prepared, according to Dr. Standke, by thoroughly washing with hot water freshly expressed castor-oil, and incorporating sufficient saccharin to give it a sweet taste; it is then flavored by adding small quantities of oil of cinnamon and extract of vanilla. The preparation is stated to keep very well, and to be very agreeable in taste.

A Post-mortem Phenomenon in Cholera.—A Vienna physician, Dr. Frey, states that the supposed burial alive of patients apparently dead from cholera may be explained by the fact that the corpses of those who have died from the disease are for some time after death subject to convulsive movements of some muscles, or even of whole groups of muscles. Professor Eichhorst also relates that on one occasion he had left a patient for dead, when, three hours later, he was told that the dead man had revived. He found that the muscles of the upper arm were giving short, quick motions, following each other rapidly, which were interrupted by contractions of the whole group of muscles, whereby the forearm was visibly contracted. The fingers were also distinctly observed to be moving, as though playing a piano. It was only after three hours that the movement of the muscles ceased.—*Hospital Gazette.*

A Dog without a Brain.—Professor Goltz, of Strasbourg, has succeeded in keeping alive three dogs, after having removed the whole of the cerebral hemispheres.

One lived fifty-one days, the second ninety-two days, and the third was killed after living eighteen months in this condition. In all three dogs the diencephalon had been more or less injured by the operation. In the case of the third dog, after he had been without his brain for over a year, he could be aroused from deep sleep through the sensation of touch. If an attempt was made to take him out of his cage, he showed signs of anger, snarled, and barked in more or less normal manner. He walked around in his cage without falling, or, if he fell on a slippery surface, he got up again without assistance. These movements were particularly energetic when the animal was hungry. The hearing, although very dull, was preserved; and he could be waked out of sleep by a loud noise. In the same way, the sight, although nearly gone, was sufficient to perceive a bright light. He could not smell at all; but his taste was not destroyed, as was shown by his declining to eat meat strewed with quinine. He could eat and drink, that is, his tongue, jaw, and pharynx moved like those of a normal dog; but food had to be put in his mouth, as he never made any attempt to get it for himself. There was entire absence of all those characteristics which are understood as intelligence, reflection, or understanding, but he could not be considered as a mere reflex mechanism. He had as much perception as a newborn infant. He was uneasy when he was hungry, and appeared satisfied after being fed. He became angry if he was waked from sleep or if he was pinched. The author believes that these experiments may modify many commonly accepted theories of the functions of the cerebral cortex—*Boston Medical and Surgical Journal.*

Insanity of an Asylum Superintendent.—A correspondent of a Vienna paper says that one morning the medical superintendent of a large lunatic asylum requested an attendant to hand him a pair of scissors. He noticed something unusual in the appearance of his chief and drew the attention of one of the physicians to the circumstance. The latter was somewhat surprised when the superintendent announced that it was his intention to open the skulls of some of his patients in order to ascertain the exact condition of their cerebral development. No time was lost in putting a limit to the scientific aspirations of the gentleman.

Taking an Advertiser at His Word.—A decision is reported by the London *Times* from the Court of Queen's Bench which should overwhelm the souls of many astute Americans with remorse at the thought of neglected opportunities, and which may well transfer the palm in the art of making money from New to Old England. It seems a certain company, which trades in a commodity called the "carbolic smoke-ball," had offered, as an inducement to the public to patronize their shop, a guarantee of $500 that any person using their nostrum should enjoy thereafter immunity from influenza. A woman in London took the advertisers at their word, bought and used their prophylactic, and thereafter suffered, like many of her unprotected neighbors, from an attack of influenza. The promise of immunity having thus been falsified the lady brought an action to enforce the alternative promise of a solatium of $500, and was met with a defence which put forward every possible ground of technical objection to the plaintiff's claim. The defendant pleaded that there was no contact, that if there was it was not stamped and could not be sued on, that it was a wagering contract and therefore void, and that it was a contract of insurance which was prohibited by statute. But the Court held that there was a contract, for there was a consideration received by the company in the price of the smoke-ball, and the Court added that the daily use of the article was sufficient to support the promise of remuneration. The defendant had not only issued the advertisement, but had stated "as showing their sincerity in the matter," that they had deposited £1,000 in bank, which the Court held must be taken as meaning that they were prepared to pay. The contract was also held not to require a stamp, nor to be a wagering contract, nor such an insurance contract as was regulated by statute. People who are silly enough, *The Lancet* says, in commentin on this case, to adopt a medicine simply because a trade man makes extravagant promises may thank themselve chiefly for any disappointment that ensues. Still for thi folly, which is only foolish and nothing worse, it is possibl to feel sympathy when the disappointment comes. It is pleasant alternative to learn that the dupe has been able as in the present instance, to enforce a sharp penalty, an that the process of reaping a harvest from the simplicit of one's neighbors is attended with dangers of miscarriag which must materially diminish its attractiveness in th eyes of those people who supply the popular demand fo quack medicines.

Cremation of Cholera Victims.—The London corre spondent of the *Sun* says that the agitation in England i favor of cremation in the case of all cholera victims i increasing. Sir Spencer Wells sent to the *Graphic* re cently the results of some experiments which have startling bearing upon this branch of the subject. H said that "some persons doubt whether poison can b carried through the earth for any considerable distance but the fact has been experimentally proved as to salin solutions. A salt of lithium was sown over a plot o land more than one hundred and fifty yards distant fron a well, the water of which contained no lithium. Repeate examinations were made, but it was only on the eigh teenth day that it was proved that the solution had per colated through the soil into the well. Instances of con tamination of water by animal impurities have long bee too well known, and now the specific germs of infective diseases are known to propagate in the same way. In th botanic garden of Lyons flower pots were filled with earth on June 16, 1891, and some earthworms were added in each pot with some of the sputa of tuberculous patients and fragments of lung from their dead bodies. A month afterward it was found that the earthworms con tained tubercle bacilli in large numbers, and that guinea-pigs inoculated with them soon died with general tuber culosis. Whatever the bacilli may be, whether tubercular, typhoid, or choleraic, in bodies buried in the earth, i is incontestable that earthworms, everywhere so numerous and active, may preserve the bacilli in their bodies during many months, still living and losing none of their virulent properties and power of rapid germination or reproduction. These are the grounds on which we assert that bodies after death from cholera ought to be cremated, not buried."

Beriberi prevails extensively in the Malay Peninsula.

The Water Supply of the Paris Suburbs.—The first case of cholera, cholerine, or cholera nostras which occurred in Paris this summer appeared in the Asylum of Nanterre. The water for this institution comes from Suresnes, on the Seine, a point at which the river has already received the contents of fifty-two sewers. A man, described as a confirmed drunkard, had just been admitted when he was taken ill and died, apparently from cholera. The authorities were not able, or in any case failed, to obtain any information as to his antecedents. Nanterre is a prison and also a sort of asylum for vagabonds. When the epidemic assumed a serious aspect, the number of inmates was reduced from about 4,000 to 3,000. Soon other cases occurred in the neighboring districts of Suresnes, Puteaux, and St. Denis. The Seine water from the Suresnes intake was found to contain, after filtration, 37,000 bacteria to the cubic centimetre, but the specific bacilli of cholera and of typhoid fever were not discovered. If the course of the Seine be followed to the water-intake at Marly, which is close to St. Germain, it will be found that the river has received at this point the contents of 108 sewers, including the main drains and two-thirds of the Paris sewage.

SUMMARY OF WHAT CAN BE ACCOMPLISHED IN THE TREATMENT OF CHRONIC BRIGHT'S DISEASE.[1]

By HENRY B. MILLARD, M.D.,

NEW YORK.

FOREIGN CORRESPONDING MEMBER OF THE ACADEMY OF MEDICINE, PARIS, FRANCE.

BEFORE considering what may be hoped for or accomplished in the treatment of chronic Bright's disease, it is indispensable to state with precision what pathological conditions are to be considered as coming under the name of Bright's disease, or Bright's diseases. The cases described by Bright himself were characterized by œdema or dropsy, albuminous urine, uræmic symptoms, and extensive renal changes. Yet perhaps even the greater part of the cases which are loosely called "Bright's disease," present none of these conditions except that of mild albuminuria. That physiological or normal albuminuria exists, I do not believe. I think the thorough consideration and arguments presented by Lecorché and Salamon (loc. cit.) upon this vexed question, show that it does not, and in the new edition recently published of my own work on Bright's disease, I have devoted considerable space to this important subject. Thus far, none of my arguments have been refuted.

For the purposes of this paper I shall exclude the cases of simple, mild, chronic albuminuria, such, for instance, in which the urine does not contain more than three centigrammes (about one-thirtieth of one per cent.) to the litre, which are unaccompanied by renal epithelia or casts, where there is no diminution in the amount of solids excreted, the functions of the kidneys are not deranged, and the general health does not seem to be impaired. And such cases are extremely common. I desire to state what has been and what may be the result of treatment in those cases in which organic changes in the kidney have brought about more or less grave disturbances of the health.

In advanced cirrhosis, where the interstitial tissue is contracted, and the cortex retracted and hardened, so many of the tubules must, of necessity, be obliterated or narrowed, that there would be a great loss or destruction of their investiture of epithelia, and there would not be left enough of these to enable the kidney to perform its normative functions, namely, the formation from the blood of the capillaries which surround the tubules (and often many of the capillaries are inflamed and sclerosed) of the solids which are excreted in the urine. The result of these conditions would be the excretion of the aqueous principles of the urine, containing but little solid matter in solution, and the retention in the blood of elements, which, perhaps, by their decomposition, contribute to the poisoning of the system and the irritation of the nervous centres, and, finally, the dire catalogue of the symptoms met with in advanced cirrhosis. In such cases we can ordinarily hope to accomplish nothing more than to palliate symptoms, and perhaps prolong life. Recovery or a cure is not to be looked for.

Likewise, where the kidneys have undergone considerable fatty change; in the amyloid kidney and in the large white kidney; where there is a daily loss of considerable quantities of albumin, the tubules being choked by swelled epithelia or filled with casts; where the casts from the broad tubules predominate; where the glomeruli are inflamed and incapable of separating the aqueous principles, and the urinary secretion is diminished; and where these changes are fixed and chronic, little, perhaps nothing, is to be expected in the way of a cure.

Nevertheless, between the numerous cases of mild chronic albuminuria and those of advanced cirrhosis and chronic parenchymatous nephritis, there exist many, even severe, forms of nephritis in which the structural changes are marked, and even chronic, and so great as even to produce grave conditions of health and endanger life (I do not here allude to acute nephritis), where much, perhaps everything, can be hoped for, and even expected, from well-directed therapeutics. In these cases we are not confronted by a condition of abject helplessness, but may address ourselves to the work of relief strengthened by a certain sense of power.

When the epithelia are destroyed, they are never restored, their place being taken by a new formation of flat, spindle shaped cells—endothelia—between the basis of the epithelia and the so-called structureless membrane; sometimes nucleated, though more frequently not. These may be embryonic or aborted epithelia. Of course it is no more possible to produce a new growth of epithelia than it is to restore hardened connective tissue or contracted or shrunk up glomeruli to their normal state. This must be conceded.

But in all chronic cases which are susceptible of cure there is an intercurrence of acute or subacute inflammation; and this it is which I believe we cure or arrest; and that in chronic nephritis there is a constant effort to develop these new inflammations. The cirrhosis, the destroyed tubules, the obliterated tufts, these conditions must remain. But this being the case, can a cure be expected?

I answer that even then there are cases which are susceptible of a practical cure, or, at least, to such an extent that the renal functions will be unimpaired, the nutrition of the system will be unaffected, and no symptoms referable to the kidneys will exist. This is possible: 1. Because only a moderate amount of interstitial tissue may be affected, and so few of the tubules, as to leave sufficient healthy epithelia to enable the kidney to perform its functions. So long as this condition is equable and constant, no perturbation is experienced; but when, in addition, the epithelia become more or less extensively involved by inflammation, and proliferation and inflammation of the interstitial tissue occurs, and with the increased activity of the renal there is polyuria, increased albuminuria, and diminished formation of solids, then it is that the innumerable symptoms of the morbus Brightii are developed. 2. Cirrhoses may exist only in a mild degree, and sometimes only in patches. There are cases in which the organic changes are limited to one kidney. Now, it is under these three conditions, in which the great part of the cures of Bright's disease are brought about. I have no doubt that the new inflammations can usually be controlled; and when this is done the renal symptoms and deviations from health disappear.

Of course I except cases of great structural changes in the kidney. As in all organic diseases, everything depends upon the *amount* of disease.

I have treated many cases of chronic nephritis in which

[1] Sommaire de ce que l'on peut accomplir dans le traitement de la maladie chronique de Bright. Read before the Academy of Medicine of Paris, September 6, 1892.

disturbances of vision, loss of strength and weight, headaches, œdema, nausea, and polyuria, variously existed; the patients that I have so treated have been under my observation for several years, and, so far as renal symptoms are concerned, are in the enjoyment of perfect health. In some of these cases the albuminuria has completely disappeared. A few of these cases I will briefly describe.

About twenty years ago, a young lady, then sixteen years of age, had suffered for about six months from all the conditions of chronic catarrhal nephritis. An absolute cure was effected in six months, and her health has remained, and is now, perfect.

Another case is that of a gentleman who had been incapacitated from work for a year, from chronic interstitial nephritis. There was slight albuminuria, great debility, hard tense pulse, with severe circulatory disturbances of the head. Has enjoyed now perfectly good health for about three years.

A third case is that of a gentleman, aged forty-two, of somewhat scrofulous constitution. First consulted me in 1885. There was chronic interstitial nephritis, and he had been incapacitated for work for three years. There was great debility, considerable cardiac tension, and loss of flesh. Within the last three years he has gained sixteen pounds, is strong and able to attend to business. Albumin is, however, always present, varying from $\frac{1}{10}$ to $\frac{1}{100}$ of one per cent. For two or three years there have been no renal epithelia.

The next patient I will refer to was a lady, who had been suffering from chronic nephritis for more than a year. It followed uræmic convulsions, she having had these in four different confinements. There were abundant casts, kidney epithelia, and from one-tenth to one-twentieth of one per cent. of albumin. For five years now there has not been a trace of albumin, and her health has been perfectly good. The microscope in this case showed more croupous than interstitial nephritis.

A girl, fourteen years of age, suffering from the chronic interstitial nephritis of malarial poisoning, was placed under my care nearly eleven years ago. The malady had been recognized about a year before I saw her. There were severe headaches, subsultus tendinum, threatening convulsions, debility, and always about one-thirtieth of one per cent. of albumin. For eight years now there has been no albumin, and the health has been perfectly good.

I mention these cases as illustrations of what I consider cures in grave conditions of renal cirrhosis or parenchymatous nephritis, and I could mention a considerable number of others.

Undoubtedly, were it possible for me to make now a microscopic examination of the kidneys of these patients, I should find more or less thickened and hardened interstitial tissue, obliteration of a greater or less number of renal tubules, some tubules partially stripped of their epithelia, and others partially obliterated, and perhaps thickening of Bowman's capsule and destruction or atrophy of some of the tufts. But I should expect to find no acute nor subacute inflammatory conditions, and I should find enough healthy epithelia and tufts to separate the urinary salts and aqueous principles in their normal quantity. In a word, the healthy tissue would be so much in excess of that destroyed or useless that the loss of the latter would do no harm.

Thus I have endeavored to give a summary of what may be accomplished in the treatment of chronic nephritis; certainly a much more cheerful summing up than can be given of phthisis and many other grave diseases, and, on the whole, affording much that is cheering in itself.

The ordinary chronic, harmless albuminuria of years' standing, proceeding for instance from the glomeruli without any lesions of the urinary tubules, can seldom, if ever, be cured, and I will go so far as to say that in the majority of cases it matters but little whether it be cured or not.

In chronic croupous nephritis with dropsy, in the large white kidney, or the fatty kidney, the prospects of benefit from treatment are much less than in the mild cirrhotic kidney. My experience in these cases has usually been unsatisfactory, and I believe that the possibilities of what I will continue to call a cure are very small. Nevertheless, I have records of several cases of chronic tubal nephritis of more than a year's standing, with dropsy, which were radically cured, the albumin entirely disappearing. Of course these were not cases of the large white or fatty kidney, but were undoubtedly cases of simple tubal nephritis. There was, in these cases, considerable albuminuria, numerous renal epithelia and casts, mostly granular, many of them having undergone fatty degeneration.

Chronic parenchymatous nephritis I have found more favorable to treatment when it has resulted from paludal poisoning; I have found iron, arsenic, and quinine of great value in these cases.

Another class of cases in which treatment may yield highly satisfactory results is where the nephritis has had a specific origin.

I have given, in the third edition of my work on Bright's disease, the details of what is practically a complete cure of a grave case of chronic interstitial nephritis of syphilitic origin. The patient had been under treatment for nearly two years before he consulted me; he had for several months been incapacitated from attending to business, and suffered from debility, headaches, and dimness of vision; there was considerable œdema of the eyelids; there were at no time casts, and but few renal epithelia. Two or three years of treatment were, however, necessary to bring about a good condition of health. I will say that for many months he took from forty to eighty grains of the iodide of potash daily, besides taking Fowler's solution in large doses and corrosive sublimate, as well as the proto-iodide and ben-iodide of mercury.

I will say no more at present as to what may be expected in the relief or cure of chronic Bright's disease. I am glad that I am able to say so much that is favorable. I am aware that many physicians regard all cases of chronic nephritis as being beyond the pale of relief. But there is no reason why chronic inflammatory conditions of the kidney may not yield to treatment in a like proportion with other chronic inflammatory conditions, as of the lungs, cirrhosis of the liver, etc. Dr. Millard, of Paris, has published an account of three cases of the latter which he has cured.

As to acute Bright's disease, I will only say that it may be placed in the list of curable diseases. There are but few cases that with proper treatment may not be perfectly cured.

But when I say that many cases of chronic nephritis may be cured, it is not to be inferred that a cure is always easy, or to be effected without the expenditure of a great deal of labor and time on the part both of the physician and patient. Circumstances must favor the latter, in enabling him to pursue the treatment uninterruptedly for as long a time as is necessary; if needed, to take rest from work, to avail himself of a course of mineral waters, or a change of climate. Thorough chemical and microscopic examinations of the urine must be frequently made, so as to take advantage of every change in the renal conditions; the diet, selected with care, must be rigorously observed; hot air or vapor baths I consider indispensable. Whenever a new case of much gravity is presented to me, I usually require the patient to keep his bed perhaps for several weeks, and to subsist on a lacteal, or on a slightly nitrogenous, diet. It is necessary to make the patient understand *in limine* the necessity of all this, and that he has before him a long and arduous course of treatment. Unless patients comprehend all these necessities I cannot give them much encouragement, and prefer not to treat them.

It is not the purpose of this paper to refer specifically to the treatment, but I will say that, together with the

measures I have referred to, I have found various mercurial preparations indispensable, and I have used with great value ergotinine, caffeine, strophanthus, digitalis, sparteine, arsenic, various preparations of iron, especially the albuminate and chloride, quinine, the salts of strontium and calcium, nitro-glycerine, iron and arsenical waters of the Trentino, as the Levico and Roncegno, and diuretics. If uric acid exist in excess I neutralize it by Vichy, Vals, or similar waters, and often prescribe for the same purpose Schering's piperazine water with phenocoll. I send patients often to Evian, Vichy, or Royat, and, if the hepatic functions are greatly deranged, to Carlsbad, Marienbad, or Vichy.

I will close by quoting from my own work the following remarks upon treatment :

"There is a harmful disposition on the part of writers, even of known ability, in reviewing the therapeutics of Bright's disease, to speak of the employment of a long list of remedies in this ailment, and of finding them in certain cases useless or the contrary. Practically, their conclusions are to the effect that such and such remedies are 'good' or are not 'good for' or *in* Bright's disease. The mistake that such writers make is in considering this malady an *entity* and treating it as such, instead of realizing its multiple character and the fact that the pathological conditions, the changes, the constitution of the disease, the etiology, are seldom identical in different cases; although it is of course true that there is a certain number and class of remedies without recourse to which treatment would be likely to prove unavailing."

THE BIOLOGICAL CHARACTERS OF THE CHOLERA SPIRILLUM—SPIRILLUM CHOLERÆ ASIATICÆ ("COMMA BACILLUS" OF KOCH)—AND DISINFECTION IN CHOLERA.

By GEORGE M. STERNBERG, M.D.,

DEPUTY SURGEON-GENERAL U. S. ARMY.

It is now eight years since Koch discovered (1884), in the excreta of cholera patients and in the contents of the intestines of recent cadavers, the pathogenic micro-organism which he first described as a "comma bacillus." Some bacteriologists now speak of this micro-organism as the cholera "vibrio;" but we prefer to follow the nomenclature of Flügge, who describes it under the specific name Spirillum choleræ Asiaticæ; for under certain circumstances it grows out into long spiral filaments, and the so-called "commas" have a spiral twist which may be recognized in drop cultures, especially in the longer elements which in stained preparations present an S shape. When development is rapid the short curved rods and S-shaped spirals only are seen; but in hanging-drop cultures, or in media in which the development is retarded by unfavorable conditions, such as a low temperature or the presence of a small amount of alcohol, long spiral filaments are quite numerous. In old cultures various distorted forms are frequently seen—so-called involution forms. The curved rods have rounded extremities and are about 0.3 to 0.4 μ in diameter. They are actively motile, and are provided with a single terminal flagellum, which may be demonstrated by Löffler's method of staining.

FIG. 1.—Spirillum Choleræ Asiaticæ. (1,000.) From a photomicrograph. (Koch.)

Before speaking of the biological characters of this spirillum it may be well to say a word with reference to its etiological relation to the disease with which it is associated. This is now generally admitted by pathologists. So far as I am informed there has been no failure to find it in the characteristic discharges of cholera patients when these have been collected at an early period of the attack and have been examined by competent bacteriologists. On the other hand, this particular spirillum has never been obtained from the alvine discharges of persons suffering from other diseases or of healthy individuals, although very extended bacteriological examinations of such material have been made since its discovery. Among these I may mention the researches of Finkler and Prior,[1] of Weisser,[2] of Escherich,[3] of Booker,[4] of Jeffries,[5] and my own [6] extended study of the dejecta of yellow-fever patients, and of healthy persons, for comparison. Many bacteriologists have also made examinations of the excreta of typhoid-fever patients, and of well and river water from various sources, but no one has encountered a spirillum which is identical with the "comma bacillus" of Koch. It is true that two closely allied micro-organisms have been found; one, the spirillum of Finkler and Prior, found in the dejecta of certain cases of cholera nostras, and the other the spirillum of Deneke, obtained in 1885 from a piece of old cheese; but both of these have been shown to present constant characters by which they may be differentiated from Spirillum choleræ Asiaticæ.

It is but fair to state that Cunningham,[7] as a result of recent (1891) researches made in Calcutta, states that he has failed to find comma bacilli in undoubted cases of cholera, and that in certain cases in which they were present he was able to differentiate several varieties.

With reference to the experimental evidence of the pathogenic power of this spirillum I must refer you to the extended literature of the subject. That recent cultures are pathogenic for certain of the lower animals, and especially for guinea-pigs, has been amply demonstrated by the experiments of Koch and others.

It has also been ascertained that cultures recently obtained from the dejecta of cholera patients are more pathogenic than those which have been carried through a long series of cultivations in the usual artificial media.

Brieger has succeeded in isolating several toxic ptomaines from cultures of the cholera bacillus, some of which had previously been obtained from other sources—cadaverin, putrescin, creatinin, methyl-guanidin. In addition to these he obtained two toxic substances not previously known. One of these is a diamin, resembling trimethylenediamin; it gave rise to cramps and muscular tremor in inoculated animals. The other poison reduced the frequency of the heart's action and the temperature of the body in the animals subjected to experiment. In more recent researches made by Brieger and Fränkel [8] (1890) a toxalbumin was obtained from cholera cultures, which, when injected subcutaneously into guinea-pigs, caused their death in two or three days, but had no effect on rabbits.

Pfeiffer [9] has recently (1892) published his extended researches relating to the cholera poison. He finds that recent aërobic cultures of the cholera spirillum contain a specific toxic substance which is fatal to guinea-pigs in extremely small doses. This substance stands in close relation with the bacterial cells and is perhaps an integral

part of the same. The spirilla may be killed by chloroform, thymol, or by desiccation, without apparent injury to the toxic potency of this substance. It is destroyed, however, by absolute alcohol, by concentrated solutions of neutral salts, and by the boiling temperature, and secondary toxic products are formed which have a similar physiological action, but are from ten to twenty times less potent. Similar toxic substances were obtained by Pfeiffer from cultures of Finkler-Prior's spirillum, and from Spirillum Metschnikovi.

The spirillum is not found in the blood or in the various organs of individuals who have succumbed to an attack of cholera; but it is constantly found in the alvine discharges during life and in the contents of the intestine examined immediately after death; frequently in almost a pure culture in the colorless "rice-water" discharges. It is evident, therefore, that if we accept it as the etiological agent in the disease, the morbid phenomena must be ascribed to the absorption of toxic substances formed during its multiplication in the intestine. In cases which terminated fatally after a very brief sickness Koch found but slight changes in the mucous membrane of the intestine, which was slightly swollen and reddened; but in more protracted cases the follicles and Peyer's patches were reddened around their margins, and an invasion of the mucous membrane by the "comma bacilli" was observed in properly stained sections. They penetrated especially the follicles of Lieberkühn, and in some cases were seen between the epithelium and basement membrane. As a rule, the spirillum is not present in vomited matters, but Koch found it in small numbers in two cases, and Nicati and Rietsch in three. In about one hundred cases in which Koch examined the excreta or the contents of the intestine of recent cadavers, during his stay in Egypt, in India, and in Toulon, his "comma bacillus" was constantly found, and other observers have fully confirmed him in this particular.

The most satisfactory evidence that this spirillum is able to produce cholera in man is afforded by an accidental infection which occurred in Berlin (1884) in the case of a young man who was one of the attendants at the Imperial Board of Health, when cholera cultures were being made for the instruction of students. Through some neglect the spirillum appears to have been introduced into his intestine, for he suffered a typical attack of cholera, attended by thirst, frequent watery discharges, cramps in the extremities, and partial suppression of urine. Fortunately he recovered, but the genuine nature of the attack was shown by the symptoms, and by the abundant presence of the "comma bacillus" in the colorless, watery discharges from the bowels.

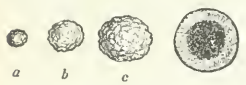

FIG. 2.—Colonies of the cholera spirillum. *a*, End of twenty hours; *b*, end of thirty hours; *c*, end of forty-eight hours; *d*, after liquefaction of the gelatin. (Flügge.)

I shall not detain you with an account of the characters of growth in various culture media which enable bacteriologists to recognize this particular spirillum, but will call your attention more particularly to those biological characters which are of interest from a practical point of view, as furnishing a scientific basis for measures of prophylaxis, disinfection, etc.

The cholera spirillum grows readily in a variety of organic media, either in the presence or in the absence of oxygen. In other words, it is an aërobic and facultative anaërobic spirillum.

In bouillon the development is rapid and abundant, especially in the incubating oven; the fluid is only slightly clouded, but the spirilla accumulate at the surface, forming a wrinkled membranous layer. Sterilized milk is also a favorable culture medium. In general this spirillum grows in any liquid containing a small quantity of organic pabulum and having a slightly alkaline reaction. An acid reaction of the culture medium prevents its development, as a rule, but it has the power of gradually accommodating itself to the presence of vegetable acids, and grows upon potatoes—in the incubator only—which have a slightly acid reaction. Abundant development occurs in bouillon which has been diluted with eight or ten parts of water, and the experiments of Wolffhügel and Riedel show that it also multiplies to some extent in sterilized river and well water, and that it preserves its vitality in such water for several months. According to Kinyoun it may preserve its vitality in sterilized sea-water, taken from New York Bay, for a considerable time, but not for a longer period than sixty days.

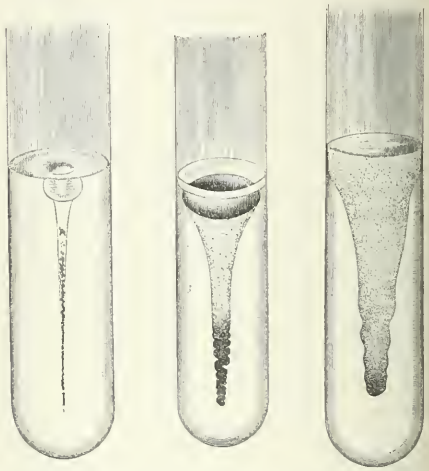

FIG. 3.—Cultures in Nutrient Gelatin at the Room Temperature (16° to 18° C.) at the Commencement of the Fourth Day. *a*, Spirillum cholerae Asiaticæ; *b*, Spirillum tyrogenum; *c*, Spirillum of Finkler and Prior. (Baumgarten.)

In an extended experimental research made by De Giaxa[1] (1889), it was found that in sterilized sea-water the cholera spirillum multiplied abundantly for a time, and retained its vitality for a considerable period; but in non-sterilized sea-water it died out within two or three days, the rapidity with which it disappeared depending upon the number of common saprophytes in the water. It has also been found that it dies out within a few days in milk or in river water, which contains numerous saprophytic bacteria.

Gruber and Schottelius have shown that in bouillon which is greatly diluted the cholera spirilla may take the precedence of the common saprophytic bacteria, and that they form upon the surface of such a medium the characteristic wrinkled film. Koch found in his early investigations that rapid multiplication may occur upon the surface of moist linen, and also demonstrated the presence of this spirillum in the foul water of a "tank" in India, which was used by the natives for drinking purposes. In the experiments of Bolton (1886) the cholera spirillum was found to multiply abundantly in distilled water to which bouillon was added in the proportion of fifteen to twenty-five parts in one thousand.

The thermal death-point of the cholera spirillum in recent cultures in flesh-peptone-gelatin, as determined by the writer[2] (1887), is 52° C., the time of exposure being four minutes; a few colonies only developed after exposure of a temperature of 50° C. for ten minutes. In Kitasato's experiments (1889) ten or even fifteen minutes' exposure to a temperature of 55° C. was not always successful in destroying the vitality of the spirillum, although

[1] De Giaxa: Ueber das Verhalten einiger pathogener Mikroorganismen im Meerwasser. Zeitschr. fur Hygiene, Bd. vi., 1889, p. 162.

[2] Sternberg: The Thermal Death-point of Pathogenic Organisms. American Journal of the Medical Sciences, Philadelphia, xciv., 1887, p. 146.

in certain cultures exposure to 50° C. for fifteen minutes was successful. He was not, however, able to find any difference between old and recent cultures as regards resistance to heat or to desiccation. In a moist condition this spirillum retains its vitality for months—as much as nine months in agar and about two months in liquefied gelatin. It is quickly destroyed by desiccation, as first determined by Koch, who found that it did not grow after two or three hours when dried in a thin film on a glass cover. In Kitasato's[1] experiments (1889) the duration of vitality was found to vary from a few hours to thirteen days, the difference depending largely upon the thickness of the film. When dried upon silk threads they may retain their vitality for a considerably longer time (Kitasato). Very numerous experiments have been made to determine the amount of various disinfecting agents required to destroy the vitality of this micro-organism. We give below the results recently reported by Boer[2] (1890), whose experiments were made in Koch's laboratory. Experiments upon a culture in bouillon kept for twenty-four hours in the incubating oven, time of exposure, two hours: Hydrocyanic acid, 1 to 1,350; sulphuric acid, 1 to 1,300; caustic soda, 1 to 150; ammonia, 1 to 350; mercuric cyanide, 1 to 60,000; gold and sodium chloride, 1 to 1,000; silver nitrate, 1 to 4,000; arseniate of soda, 1 to 400; malachite green, 1 to 5,000; methyl violet, 1 to 1,000; carbolic acid, 1 to 400; creolin, 1 to 3,000; lysol, 1 to 500. In Bolton's experiments (1887) mercuric chloride was effective in two hours in the proportion of 1 to 10,000; sulphate of copper, 1 to 500.

The low thermal death-point and comparatively slight resisting power for desiccation and chemical agents indicate that this spirillum does not form spores, and most bacteriologists agree that this is the case. Hueppe, however, has described a mode of spore formation which is different from that which occurs among the bacilli, viz., the formation of so-called arthrospores; these are said to be developed in the course of the spiral threads, not as endogenous refractive spores, but as spherical bodies which have a somewhat greater diameter than the filament and are somewhat more refractive. This mode of spore formation has not been observed by Kitasato and other bacteriologists who have given attention to the question, and cannot be considered as established. In competition with the ordinary putrefactive bacteria the cholera spirillum soon disappears, and, as determined by Neffelman and by Kitasato, they only survive for a few days when mixed with normal fæces.

The cholera spirillum grows best at a temperature of 30° to 35° C., and ceases to grow at a temperature above 42° C., or below 14° C. Like other micro-organisms of this class, it is not destroyed by a freezing temperature.

The experimental data already referred to indicate heat, strong mineral acids, carbolic acid, and certain other agents named as being available for the destruction of the cholera spirillum, wherever it may be found outside of the bodies of infected individuals. The question as to what agents it is best to recommend for general use as practical disinfectants will, of course, depend upon certain facts relating to cost, poisonous properties, odor, action upon metals, etc.

After considering all of these circumstances, the Committee on Disinfectants[3] of the International Sanitary Conference of Rome selected carbolic acid and chloride of lime as the most available and reliable chemical disinfectants, and gave the following directions for their use:

Disinfection.—5. The commission recommends, as a means of disinfection against cholera, besides destruction: 1, Steam at 100° C.; 2, carbolic acid, chloride of lime; 3, aëration.

Carbolic acid and chloride of lime are to be used in aqueous solution:

Weak Solutions: Carbolic acid, two per cent.; chloride of lime, one per cent.

Strong Solutions: Carbolic acid, five per cent.; chloride of lime, four per cent.

These means of disinfection will be applied as follows:

I. For the disinfection of persons, the weak solutions should be employed.

II. For the disinfection of clothing, bedding (*des linges, aes habits, des couvertures*), and other articles of this kind: *a*, destruction; *b*, steam passed through the articles for one hour; *c*, boiling for thirty minutes; *d*, immersion for twenty-four hours in one of the weak disinfecting solutions; *e*, aëration for three or four weeks, but only in case the other means recommended are inapplicable.

Articles of leather, such as trunks, boots, etc., should be either destroyed, or washed several times with one of the weak disinfecting solutions.

III. Vomited matters and the dejections of the sick should be mixed with one of the strong disinfection solutions, in quantity at least equal to the amount of material to be disinfected. Linen, clothing, bedding, etc., recently soiled by the dejections of the sick, which cannot be immediately subjected to the action of steam, should be at once immersed in one of the strong disinfecting solutions, and left for four hours.

IV. The dead should be enveloped in a sheet, saturated with one of the strong disinfecting solutions, without previous washing of the body, and at once placed in a coffin.

V. Disinfection of merchandise, and of the mails is unnecessary (steam under pressure is the only reliable agent for the disinfection of rags—*les chiffons en gros*).

VI. When cases of cholera occur upon a vessel at sea, the locality where the case occurs should be disinfected. The floors and walls of the cabin, or other locality, should be washed at least twice with one of the weak disinfecting solutions, and then exposed freely to fresh air.

In the case of objects of considerable value, which have not been in immediate contact with the sick, and which would be seriously injured by a rigorous disinfection, the physician on board may determine what measures are necessary to protect the sanitary interests of the vessel.

The bilge-water should be pumped out, and replaced by sea-water, at least twice at each disinfection of a vessel.

The closets should be well washed with one of the strong disinfecting solutions, at least twice a day.

VII. If the drinking-water is open to suspicion, it should be boiled before it is used, and the boiling should be repeated if it is not used within twenty-four hours.

All suspected food should be destroyed, or at least recently cooked.

VIII. Hospitals should be disinfected by washing the floors and walls with one of the weak disinfecting solutions, by a subsequent free ventilation and cleansing, and finally by repainting. The wards to be disinfected should, as far as possible, be isolated from those in use.

The latrines should be disinfected at least twice a day, by pouring into them the strong disinfecting solutions in quantity at least equal to the amount of the dejections received since the last disinfection.

IX. The clothing worn by physicians and attendants should remain in the hospital, and should be regularly disinfected.

Physicians and attendants should use the weak disinfecting solutions for washing their hands, etc.

Carbolic Acid possesses the advantage of not being neutralized by the substances found in excreta, or by the presence of albumin. In experiments made by Bolton under my direction (1885) it was found that the addition of ten per cent. of dried egg albumin to a bouillon cult-

[3] This committee consisted of Koch, of Germany; Sternberg, of the United States; Proust, of France; Thorne Thorne, of England; Eck, of Russia; Hoffmann, of Austria; and Semmola, of Italy. The report of the committee was adopted unanimously by the Conference.

ure of the typhoid bacillus did not materially influence the disinfecting power of this agent, the bacillus being destroyed in two hours by a one per cent. solution. The experimental evidence therefore fully justifies the recommendations of the Committee on Disinfectants of the International Sanitary Conference of Rome, and of the health officials of Europe and America, which direct the use of a five per cent. solution of carbolic acid for the disinfection of dejecta, and of a two per cent. solution for soiled linen and other clothing which can be immersed in a disinfecting solution without injury.

I know of no objection to the use of this agent as directed except its comparative cost.

Chloride of Lime which is placed beside carbolic acid in the recommendations adopted by the International Conference of Rome, is considerably cheaper and equally effective. The Committee on Disinfectants of the American Public Health Association (1887) gave it "the first place for disinfecting excreta, on account of the rapidity of its action." This recommendation was based upon experimental data obtained in the Biological Laboratory of the Johns Hopkins University, under the writer's direction, and is sustained by more recent experiments made in Germany.

The experiments of Bolton,[1] made for the Committee on Disinfectants in 1886, gave the following results: The time of exposure being two hours, the typhoid bacillus and cholera spirillum in bouillon cultures were killed by a solution containing 1 to 1,000 parts of water (containing 0.03 per cent. of available chlorine). Anthrax spores were killed in the same time by a solution containing 0.3 per cent. of available chlorine. Typhoid fæces were sterilized by a two per cent. solution, and in several instances by a one-half per cent. solution; but some resistant spores of non-pathogenic bacilli survived in two experiments in which a solution of 1 to 100 was used. In bouillon cultures to which ten per cent. of dried egg albumin had been added the typhoid bacillus was destroyed by one-half per cent. (1 to 200).

Nissen,[2] whose experiments where made in Koch's laboratory in 1890, found that anthrax spores were destroyed in thirty minutes by a five per cent. solution, and in seventy minutes by a one per cent. solution. In his experiments the typhoid bacillus and the cholera spirillum were destroyed with certainty in five minutes by a solution containing 0.12 per cent. (1 to 833); the anthrax bacillus in one minute by 1 to 1,000; staphylococcus pyogenes aureus in one minute by 1 to 500.

Experiments made by the same author on the sterilization of fæces showed that one per cent. could be relied upon to destroy the bacillus of typhoid fever and the spirillum of cholera in fæces in ten minutes.

Another agent of great value for the disinfection of excreta is recently-burned quick-lime. Experiments made in Koch's laboratory in 1887, by Liborius, led him to place a high value upon this agent as a disinfectant. More recent experiments by Jaeger, Kitasato, Pfuhl, and others, have shown that caustic lime has considerable germicidal power in the absence of spores, and that the value which has long been placed upon it for the treatment of excrementitious material in latrines, etc., and as a wash for exposed surfaces is justified by the results of exact experiments made upon known pathogenic bacteria. The germicidal power of lime is not interfered with by the presence of albuminous material, but is neutralized by phosphates, carbonates, and other bases, and by carbonic acid.

In the writer's experiments a saturated aqueous solution of calcium oxide failed to kill typhoid bacilli; but when suspended in water in the proportion of one to forty by weight, this bacillus was killed at the end of two hours. Anthrax spores were not killed in the same time by a lime wash containing twenty per cent. by weight of pure calcium oxide. According to Kitasato the typhoid bacillus and the cholera spirillum in bouillon cultures are destroyed by the addition of 0.1 per cent. of calcium oxide. Pfuhl experimented upon sterilized fæces, to which pure cultures of the typhoid bacillus or cholera spirillum were added. The liquid discharges of patients with typhoid fever or diarrhœa were used for the purpose. He found that sterilization was effected at the end of two hours by adding fragments of calcium hydrate in the proportion of six per cent., and that three per cent. was effective in six hours. When a milk of lime was used which could be thoroughly mixed with the dejecta, the result was still more favorable. A standard preparation of milk of lime containing twenty per cent. of calcium hydrate killed the typhoid bacillus and the cholera spirillum in one hour, when added to liquid fæces in the proportion of two per cent.

The experiments with this agent show that time is an important factor and that much longer exposures, as well as stronger solutions, are required to destroy pathogenic bacteria than is the case with the chloride of lime. For this reason we still give the last named agent the preference for the disinfection of excreta in the sick room. But in latrines the time required to accomplish disinfection is of less importance, and we are disposed to give recently-burned quick-lime the first place for the disinfection of excreta in privy vaults, or on the surface of the ground. It may be applied in the form of milk of lime, prepared by adding gradually eight parts, by weight, of water to one part of calcium hydrate. This must be freshly prepared, or protected from the air to prevent the formation of the inactive carbonate of lime.

According to Behring, lime has about the same germicidal value as the other caustic alkalies, and destroys the cholera spirillum and the bacillus of typhoid fever, of diphtheria, and of glanders, after several hours' exposure, in the proportion of 50 c.c. normal-lauge per litre. Wood ashes or lye of the same alkaline strength may therefore be substituted for quick-lime.

The recommendations of the Committee on Disinfectants of the International Sanitary Conference of Rome made no reference to the use of a germicidal agent of great value which has been largely used in this country, viz., to mercuric chloride. One reason for the omission was that the two chemical agents named were considered sufficient and satisfactory disinfectants, so far as cholera is concerned, and another reason was that certain members of the committee hesitated to recommend this agent for general use on account of its poisonous properties. So far as I know no accidents have resulted from its extended use in this country, in accordance with the recommendations of the Committee on Disinfectants of the American Public Health Association; and as a disinfecting wash for surfaces, etc, there can be no doubt of its value. The recommendations of the Committee last referred to are as follows:

For Clothing, Bedding, etc.—*a.* Soiled underclothing, linen, etc.: 1, Destruction by fire, if of little value; 2, boiling for at least half an hour; 3, immersion in a solution of mercuric chloride of the strength of 1 to 2,000 for four hours; 4, immersion in a two per cent. solution of carbolic acid for four hours.

b. Outer garments of wool or silk, and similar articles which would be injured by immersion in boiling water, or in a disinfecting solution: 1, Exposure in a suitable apparatus to a current of steam for ten minutes; 2, exposure to dry heat at a temperature of 110° C. (230° F.) for two hours.

c. Mattresses and blankets soiled by the discharges of the sick: 1, Destruction by fire; 2, exposure to superheated steam, 105° C. (221° F.) for ten minutes; 3, immersion in boiling water for half an hour.

Furniture, and Articles of Wood, Leather, and Porcelain.—Washing, several times repeated, with 1, solution of carbolic acid, two per cent.

For the Person.—The hands and general surface of

[1] Bolton: Report of Committee on Disinfectants, American Public Health Association, 1887, p. 153.

[2] Nissen: Ueber die Desinficirende Eigenschaft des Chlorkalkes. Zeitschrift für Hygiene, Bd. viii., p. 63.

the body of attendants on the sick, and of convalescents, should be washed with: 1, Solution of chlorinated soda diluted with nine parts of water, 1 to 10; 2, carbolic acid, two per cent. solution; 3, mercuric chloride, 1 to 1,000.

For the Dead.—Envelop the body in a sheet thoroughly saturated with: 1, chloride of lime, four per cent; 2, mercuric chloride in solution, 1 to 500; 3, carbolic acid in solution, five per cent.

For the Sick-room and Hospital Wards.—*a.* While occupied, wash all surfaces: 1, mercuric chloride in solution, 1 to 1,000; 2, carbolic acid in solution, two per cent.

b. When vacated, fumigate with sulphur dioxide for twelve hours, burning at least three pounds of sulphur for every one thousand cubic feet of air-space in the room; then wash all surfaces with one of the above-mentioned disinfecting solutions, and afterward with soap and hot water; finally throw open doors and windows, and ventilate freely.

For Merchandise and the Mails.—The disinfection of merchandise and of the mails will only be required under exceptional circumstances; free aëration will usually be sufficient. If disinfection seems necessary, fumigation with sulphur dioxide will be the only practical method of accomplishing it without injury.

Rags.—*a.* Rags which have been used for wiping away infectious discharges should be burned.

b. Rags collected for the paper-makers during the prevalence of an epidemic should be disinfected before they are compressed in bales by: 1, exposure to superheated steam of 105° C. (221° F.) for ten minutes: 2, immersion in boiling water for half an hour.

Ships.—*a.* Infected ships at sea should be washed in every accessible place, and especially in the localities occupied by the sick, with: 1, solution of mercuric chloride, 1 to 1,000: 2, solution of carbolic acid, two per cent.

The bilge should be disinfected by the liberal use of a strong solution of mercuric chloride.

b. Upon arrival at a quarantine station, an infected ship should at once be fumigated with sulphurous acid gas, using three pounds of sulphur for every one thousand feet of cubic air-space; the cargo should then be discharged on lighters; a liberal supply of the concentrated solution of mercuric chloride (four ounces to the gallon) should be thrown into the bilge, and at the end of twenty-four hours the bilge-water should be pumped out and replaced with pure sea-water: this should be repeated. A second fumigation, after the removal of the cargo, is recommended; all accessible surfaces should be washed with one of the disinfecting solutions heretofore recommended, and subsequently with soap and hot water.

For Railway Cars.—The directions given for the disinfection of dwellings, hospital wards, and ships apply as well to infected railway cars. The treatment of excreta with a disinfectant, before they are scattered along the tracts, seems desirable at all times, in view of the fact that they may contain infectious germs. For this purpose the standard solution of chloride of lime is recommended.

Exhibit of Anthropology.—Professor F. W. Putnam, of Cambridge, Mass., is superintendent of a large exhibit of anthropology at the coming World's Fair in Chicago. The department is to occupy the northern half of the gallery of the main building, and also a strip of land along the lagoon, where groups of native American people will be quartered in their natural habitations. There will be a representative exhibit of the remains of historic man in America, and large models of the most noteworthy of their works, such as the Serpent Mound and Fort Ancient. Central America will be well represented. Along with this there will be an exhibition of primitive industries, customs, and the like.—*Chicago Medical Recorder.*

THE PROPAGATION AND PRESERVATION OF VACCINE VIRUS.

By CYRUS EDSON, M.D.,

SANITARY SUPERINTENDENT HEALTH DEPARTMENT OF THE CITY OF NEW YORK.

In January last small-pox made its appearance in New York City, after an absence of about five years. In fact, no serious outbreak of the disease has occurred since that of 1881–82. During the past six months sporadic cases of the disease have occurred almost daily. Notwithstanding the hot weather, which usually, by compelling people to open their doors and windows, thereby securing ventilation, is a powerful factor in stopping its spread, the disease is not yet stamped out. The persistence of this outbreak would lead one to believe that, during the coming winter, a large number of cases may be expected. Apropos of this, I have thought it interesting to inform the profession concerning the means taken to propagate vaccine virus in several of the principal countries of the civilized world. I do not know of any recent attempt to collate and describe the different methods in vogue in the different countries, except that made by Dr. John Brett, the Public Vaccinator of Melbourne, Australia. This gentleman I had the honor of conducting through the Health Department laboratory in this city, and of describing to him the means taken to propagate vaccine virus here. He was at the time on a tour of the world for the purpose in question, and he kindly promised to forward to me the result of his labors when they were completed. I have just received his interesting report, from which I will draw largely in the preparation of this article.

England.—The calf-lymph establishment is under the control of the Local Government Board, and has been since it was founded in 1881. The premises occupied by it consist of a large waiting-room, divided by a partition into two parts, one of which is for vaccinating children, the other for operating on calves. Behind these are the stables, fitted with brick floors, hot and cold water, and other conveniences. Everything is kept with scrupulous cleanliness. The calves range in age from six to twelve months. Their care is supervised by a veterinary surgeon, who examines them before and after inoculation. Specially designed tables are in use to which they are strapped while being inoculated and on taking of the lymph. The strain of lymph now in use is the same as that obtained in March, 1882, from a case of spontaneous cow-pox discovered on November 25, 1881, near Bordeaux, France. This strain has never been renewed, although at times considerable trouble has been experienced with it on calves. Fresh lymph is almost invariably used for inoculations, though occasionally stored lymph has to be resorted to. The inoculations are always made by means of incisions carried deeply through the skin, and not by superficial scarifications. The lymph is taken from the ninety sixth to the one hundred and twentieth hour. The vesicle is compressed by means of specially constructed forceps, the crust having been removed and discarded. For immediate vaccination, the vesicle is scraped with a blunt scalpel, and the pulp thus removed, mixed as it is with blood, epithelium, and connective-tissue cells, is used on the child. The admixture with blood is not considered detrimental in any way; indeed, it is maintained by Dr. Cory, the superintendent, that colorless lymph is rarely to be depended on. Lymph stored on points and in tubes is also contaminated with blood and connective-tissue cells. Tubes are not, as a rule, used to any extent. The stored lymph is principally used on ivory points. The animals are inoculated along the inner aspect of the thigh and on the abdomen back of the udder or scrotum. In England, more than in any other country, humanized virus is used. This is usually collected from children whose antecedents are traced as carefully as possible, and stored either in capillary tubes or on ivory points. Experience has taught us that vaccination by means of humanized virus results in a less active

sore, and protects for a longer period. The objections to its use, however, are obvious.

Belgium.—A very wide difference exists between England and Belgium in respect to the propagation, collection, and keeping vaccine virus. The calf-lymph establishment is under the control of the Minister of the Interior, who is the official head of the Department of Hygiene. The vaccine laboratory, established in 1882 at the School of Veterinary Medecine, is in one of the suburbs of Brussels, and produces a virus at the expense of the state. The virus is distributed to all public vaccinators and to medical men who demand it. The calves are from three to four months old, and should not weigh less than one hundred kilogrammes. They are carefully fed exclusively on fresh milk, and are examined previous and subsequent to their inoculation by a veterinarian. Immediately after the lymph is taken they are killed, and if the organs are found healthy the lymph is used and the calves sold as veal. The animals are inoculated over the inguinal region, which is shaved and deeply scarified. The scarifications are made with a sharp lancet in rows of five, the incisions being one and a half inch apart. The incisions being wiped free from blood, prepared glycerine pulp, hereafter described, is inserted, or else a freshly taken pulp. On the sixth, and sometimes on the fifth day, the vesicles are found sufficiently developed, showing all around them a yellowish-brown crust, with a silvery-white zone surrounded by a slight pinkish areola. The calf is placed on a table, the parts well but gently washed with warm water, and each vesicle is clamped at its base with specially devised forceps. The crust is then removed, the exuding blood wiped away, and the soft grayish pulp scraped and placed in a porcelain cup. This pulp is used to make the following preparations: (*a*) glycerine pulp; (*b*) glycerole pulp; (*c*) liquid vaccine; (*d*) dried vaccine powder. Glycerine pulp, referred to as being used to inoculate the calves, is made as follows: the pulp is placed in a mortar, thoroughly divided and triturated until it is a homogeneous mass. It is then mixed with one-third or one-half its amount of C. P. glycerine. After being thoroughly mixed it acquires a syrupy consistency, and will preserve its activity for many weeks or even for months. It is this glycerine pulp that is used to propagate the strain in the animals. Glycerole pulp is similarly prepared, except that the raw pulp is mixed with equal parts of glycerite of starch. This pulp is preserved when prepared, either between two square pieces of glass, one of which has a small circular depression in which the pulp is placed, or in small test-tubes sealed with paraffine. Each glass square contains sufficient virus to vaccinate from two to four persons, and each vial, according to its size, contains sufficient to vaccinate from ten to one hundred. Liquid vaccine is made by taking any fluid lymph which may exude after the scraping of the vesicle, and mixing it with a small quantity of the pulp and some glycerine. This is then filtered and introduced into capillary tubes. This liquid lymph is also preserved on ivory points, which are, after being charged, thoroughly dried and then coated with gum arabic. Dried vaccine powder is prepared by placing the fresh vaccine pulp in a vacuum, by which means in twenty-four hours or so it is reduced to a fine powder. This is preserved in small cardboard boxes. The experience of physicians in Belgium has taught that the pulp glycerole contained between two pieces of glass is the most reliable virus. The lymph preserved in tubes or on points has, in consequence, fallen into disuse and is seldom asked for. The Belgian method may be taken as a good exponent of the method in vogue in France and Italy. In Germany the animal is inoculated with a glycerine compound of virus, and on about the fifth day the virus is taken as follows: The animal is placed on a table and its head nearly severed from its body by a rapid stroke. When exsanguination is complete the vesicle is carefully cleansed and entirely excised, the excision being carried deep down into the connective tissue. The mass is reduced to a pulp and then mixed with glycerine or glycerite of starch, as already described in the Belgian method. Admixture with blood is severely condemned.

In Paris the popular means of vaccinating, for those who can afford it, is directly from the animal to the child. For this purpose the calf is taken to the house, a rubber cloth is spread in one of the rooms, a vesicle is tapped, and the child is vaccinated on the spot with the exudation from it. This method is characteristically Frenchy, as the hoofs of the animal are carefully polished, it is decorated with ribbons, and a silver shovel goes with it to catch the dung, if necessary.

The method in New York is in some respects unique. Animals a year to two years old are used. When possible, these are splayed heifers, as it has been found that the hides of such are thinner and develop a better pock. The animals are vaccinated on either side of the backbone, commencing at a point about two inches from the root of the tail, running along the back toward the hip bones. Four to six inoculations are made at about two inches apart. Scarifications are made with a peculiarly shaped lancet, having six or eight blades about one-eighth of an inch apart. On the fifth to the sixth day the virus is taken. The crust is discarded, and the serum, as it naturally exudes from the sore, collected on quill slips. Slight admixture with blood is not considered undesirable, but the slips for the most part are quite free from any such admixture. Occasionally capillary tubes are used, and there is some demand for them. The object of using the region on each side of the back bone is for the purpose of cleanliness, as that part of the animal is least liable to be soiled by lying down in dung and other filth. We have found virus from young adult animals more active and more certain in its results than that from calves.

The heifers are carefully examined by the department veterinarian before vaccination, and daily afterward. When the virus has been collected and the animal has regained a healthy condition, it is killed, all the internal organs examined, and if they are found to be free from disease the meat is sold, and the virus tested, *i.e.*, from six to ten primary vaccinations are performed with it to ascertain if it is active. If the test results favorably the virus is used, if not it is discarded. The excellence of New York City Health Department virus is largely due to the ability, zeal, and labor of Dr. Edward L. Pardee, in whose charge the vaccine laboratory is.

The amount of virus produced in 1891 was as follows:

The number of animals vaccinated was	148
Quill slips prepared	192,200
Ivory points prepared	17,650
Capillary glass tubes filled	595

The cost to the city of free vaccination has, during the past six years, been greatly reduced. The following table shows, per vaccination, this reduction by years:

	Cents.		Cents.
1886	34	1889	22
1887	25	1890	17
1888	21	1891	12

An Alleged Sign of Still-birth.—Dr. A. C. Moreno, writing in the *Boletin Médico de Puebla* for August, 1892, calls attention to a means of determining whether a dead infant has breathed or not, which he claims is infallible. The ciliated cylindrical epithelium of the respiratory tract extends down to the terminal bronchioles, where, he says, it becomes cubical. In an infant which has never breathed this epithelium will be found to exist, but the minute respiration begins, this is transformed into flat epithelium. The change is not a mechanical one, the author holds, but a physiological one. Hence it would be possible to determine by means of the microscope, whether an infant, whose lungs contained air, had drawn the air in by inspiration, or whether it had been forced in during an attempt at artificial respiration.

CHANCRE OF THE MOUTH.

With Statistics and a Report of Twelve Cases, Three Occurring in Children in One Family.

By E. HARRISON GRIFFIN, M.D.,

ATTENDING SURGEON OF THROAT AND NOSE DEPARTMENT OF BELLEVUE HOSPITAL, OUT DOOR POOR, NEW YORK; AND LECTURER ON DISEASES OF THROAT AT BELLEVUE HOSPITAL MEDICAL COLLEGE.

In looking over the histories of 1,200 cases of syphilis that have come under my observation in the Bellevue clinic and in my private practice, I find the report of 12 cases where the primary chancre was situated in the region of the buccal cavity. Of these 1,200 cases 29 were specific inflammation, 488 mucous patches, 155 superficial ulcerations, 159 deep ulcerations, 34 necrosis of the bones, 30 adhesion of the palate to the pharynx, 3 tertiary cicatrices of the pharynx, 2 mercurial stomatitis, 1 chancroid of lips, 65 laryngeal syphilis, and 222 that I will classify simply as cases of syphilis of the throat. Of these cases 762 were males and 438 females.

I found 3 under the age of ten.

Between	10 and 20	there were	144

The secondary and tertiary manifestations of syphilis occurring in the throat are so common and so easily recognized by the experienced physician that I will pass them over and give the histories of the primary lesions that have occurred in my practice.

Professor Bosworth kindly showed me the chapter in his new book, which is now in print, in which he has collected some very interesting histories of the primary lesion situated in the buccal cavity. Bosworth finds that Bogolguboff out of 753 cases of chancre found the primary lesion upon the tonsil in 1 case; Mauriac the primary lesion in the [locality in 2 cases. Schadek collected 68 cases of the initial lesion occurring in the fauces. Of these 68, however, in 22 the histories are so incomplete that a diagnosis is open to question; of the 46 remaining, in 34 the lesion was located upon the tonsil, and in 12 in other parts of the fauces. Petersen, Schirajeu, Gonduoin, Hulot, Spillman, Wiggleswoith, Rollet, Desnos, Belhomme and Martin, Julien, Mackenzie, Bartholomy, Merklen, Boeck, Lavallée, Hal. Legendre, Brocq, Bumstead, Peradran, Donaldson, Taylor, Thomaschewsky, Fox, Rabitsch, and Tschistjakow all report cases of the initial lesion occurring in the region of the mouth. The reports of these cases are given in full in Bosworth's new book.

The first cases I will cite are cases that have come under my observation lately. They are particularly interesting as they occurred in children, and all members of the same family.

Case I.—Male, aged nine, was brought to me April 9, 1892. He was accompanied by his father, who brought him, as he thought he was suffering from the mumps. An examination showed the submaxillary and cervical glands of the right side enlarged to the size of a bantam's egg, they were very painful, and particularly so when he masticated his food. The glands on the left side were also enlarged, but not so much as those on the right. The little patient complained of no fever or chill, and felt perfectly well except for these glands, and a sore on his lip. The sore was situated on the lower lip, slightly to the right. I found the lip swollen, and the mucous membrane of the inside red and congested. The edges of the sore were slightly indurated, but not to the extent we are accustomed to find when the primary lesion is situated on the penis. The sore was covered with a slight mucous secretion, and its edges were even with the adjoining tissue. The sore was about the size of an old-fashioned silver three-cent piece. His sore gave him very little trouble in eating, in fact, the only pain he complained of was situated at the angle of the jaw, in the region of the swollen glands.

The sore at this period had been on his lip for about ten days to two weeks. The glands had been swollen for about a week.

This history was substantiated by his father.

The chancre showed no signs of healing. An examination of his body showed the axillary and inguinal glands slightly enlarged. The appearance of his skin, April 9th, his first visit, was interesting but not decisive. I had no doubt of my diagnosis of chancre from the appearance of the sore and the accompanying glandular enlargement and the absence of fever. I cauterized the lesion to prevent, if possible, the spread of the contagion, and also warned his father to supply him with a separate towel, glass, cup, etc., and to let him sleep alone; above all, not to let him kiss anyone, and to destroy by fire the rags he used. I also removed him from school.

I cite these instructions as they will prove interesting in the subsequent cases and show how my instructions were not carried out.

The lad had been playing truant from school and had amused himself going to the dumping grounds at the foot of Seventeenth Street and East River. Here he had gone for beer in a pail for some of the laborers, receiving a few pennies for his trouble; often he would take a sip of the beer while he was carrying it back.

One of the parties that sent him must have had a mucous patch of the lip and some of the virus left on the pail inoculated the boy with the chancre, in some open cut that chanced to be on his lip. I paid a visit to this locality and found that it was customary for the men to drink directly out of the pail instead of using glasses. The way the tin is twisted at the edge of a pail makes it a perfect nest for syphilitic virus to lodge in. The tin cup is made after the same method. The tin is twisted down upon itself, in some cases it is soldered, but the soldering soon becomes defective and makes a nest for virus to lodge in. This cup is found in the public school, Central Park, and generally where water is on tap gratis. It is a relic of barbarism and should be banished, as the top of the cup could be made like a glass, molded in one round piece. The case I have cited might have inoculated the school by the stupidity in construction of this article of drink.

April 10th.—I examined the boy's skin at my office; an eruption was making its appearance.

April 12th.—The patient's chest and back were covered with a distinct syphilitic papular eruption.

Case II.—April 19th this patient's brother was brought to me for examination, to see if he had been infected. An examination at this date was negative. I dismissed him and warned him not to use his brother's towels or anything that his brother ate or drank from.

April 30th.—The same patient, aged twelve, was brought to me again, this time complaining of a pain at the angle of the jaw and a pain in deglutition, particularly in the right side. The submaxillary gland of the right side was swollen to the size of an English walnut, the left about the size of a hickory nut. The glandular swelling had begun only three days before.

An examination of the throat showed the right tonsil slightly hypertrophied and markedly congested. The congestion was confined entirely to the tonsil itself. The follicular openings of the tonsil were well defined. At the lower portion of the tonsil, in about its median line, a small ulcer could have been seen, about the size of the blunt end of an ordinary lead-pencil. The sore was covered with a white mucus, and at the first glance looked like a mucous patch, only the surrounding tissues were much more inflamed than it is customary to find connected with the presence of this lesion. The opposite tonsil was slightly inflamed. Clearing off the surface of the ulcer showed that it was very superficial and penetrated but slightly into the meshes of the tonsil.

May 10th.—Thirteen days from the appearance of the

initial lesion typical syphilitic eruption made its appearance and left no doubt of the diagnosis. An examination of the boy's body showed slight enlargement of the axillary and inguinal glands.

May 15th.—The patient troubled with headache, slight fever, and night-sweats, very much prostrated and desired to lie down all the time. These symptoms were absent in the younger case.

This case is particularly interesting, inasmuch as the inoculation took place through a stick of candy that the elder brother had put in his mouth after the younger one had sucked on it. The virus was thus carried from the lip of the one to the tonsil of the other. The date of the appearance of the sore in the second case shows that the inoculation took place previous to the first visit of his brother to the clinic, the virus being in his system, but when he was first seen the disease had not had time to develop the initial lesion.

Bosworth speaks of the open mouths of the crypts of the follicles as being a favorite site for the lodgement of syphilitic virus, the inoculation taking place by the virus being held in position, and not necessarily by a local abrasion of the tonsil.

The cases are interesting, as the chancre and the glandular swelling in the first case followed each other so quickly and in the latter appeared almost instantaneously. The history of the eruption is entirely at variance with the time that usually elapses between the presence of the chancre and the ingress of the eruption in the adult life. In the first case the eruption came out about ten to twelve days after the presence of the chancre, in the second case thirteen days after the initial lesion.

No suppuration in the cervical bubo occurred in either case. They yielded readily to treatment and disappeared almost entirely in three weeks after internal and local medication was once commenced.

In the second case the bubo reached the size of a large chicken's egg. I used internally the proto-iodidi pills, gr. $\frac{1}{6}$, and pushed to the extent of toleration. Locally I used an unguent of hydrargyri upon the enlarged glands. Oleum morrhuæ was used also in the case, as the patient was badly nourished.

Case III.—Sister of above cases, aged fifteen, applied to me, May 1st, for an examination, accompanied by her father, who said that he was beginning to be afraid himself. The examination at this time was negative.

May 10th.—The father told me that his girl's lip was swollen, accompanied by a sore.

May 15th.—The sister's upper lip was swollen and a significant sore situated in about the median line, the glands of the neck slightly enlarged, more on the right side than on the left side. An examination of the skin at this stage was negative. The sore gave her no trouble either in eating or drinking. She could eat a large pickle that had been soaked in vinegar, without the slightest pain. The lack of pain is very diagnostic of a chancre. This initial lesion reached the size of a cent before it showed any sign of healing. It extended backward and involved the inner margin of the lip.

The source of inoculation in this case was by kissing her brother. The eruption made its appearance June 5th, about twenty-six days after the initial lesion.

Case IV.—Male, aged eight, applied to me complaining of enlarged glands and a sore on the tonsil. The sore involved the lower part of the right tonsil. Its peculiar gray appearance and its irregular edge, accompanied by glandular swelling of the neck, rendered the diagnosis very simple. He had contracted it from impure practice. The history of this case was very decisive.

Case V.—Female, actress, aged twenty-four, came under my notice during the period of eruption. A slight redness of the lip located the initial lesion. She had been accustomed to make up in the same room with another member of the company. This lady suffered with a sore mouth, which my patient found out afterward to be of a syphilitic nature. They both used the same rouge for the lips, and applied it by the finger. The one suffering from the syphilitic throat must have lodged some of the virus in the rouge, and my case carried the infection to some open sore on her lip while she was preparing herself for the footlights.

Case VI.—Female, aged eighteen, came under my observation after she had consulted a notorious advertising specialist, who diagnosed her trouble as cancer of the lip and desired to operate, taking out a V incision. The nature and appearance of the sore, accompanied by the glandular swelling, rendered the diagnosis easy. The accompanying eruption substantiated it.

She caught her trouble while out with a friend on an excursion, by being kissed by an intimate acquaintance.

Case VII.—Female, aged twenty-three, applied to me for a sore lip, and the peculiar appearance of the sore and the history, accompanied later by the eruption, diagnosed chancre. She had been married but a short time. Her husband suffered from fever blisters, as she designated them, and desired to know if her throat was due to her husband's trouble.

Case VIII.—Male, aged forty-two, applied to me with a sore on the upper lip. Diagnosis, chancre, substantiated later by an enlarged cervical bubo and papular syphilitic eruption. Mode of contagion, drinking whiskey from a bottle after some of his friends at an excursion had imbibed previously from the bottle. Found out later that one member of the *soirée* had a venereal sore throat.

Case IX.—Male, aged twenty-eight, applied to me at my office for a sore throat. Diagnosis, mucous patches at the tip and side of the tongue, and also covering the inside of the lower lip. Taking his history I found he had been married six weeks, although he knew he was suffering from syphilis. I cauterized the sores and positively forbade him kissing his wife. I gave also internal medication. This patient drank, smoked, chewed, and partook of all the vices of the calendar.

Three weeks later he brought his wife to see me; he had disobeyed my instructions and had inoculated his wife with a chancre on the under portion of the tongue. The wife came out later with an extensive tubercular eruption, large ulcerative spots covered her back and breast, it was a case of malignant syphilis.

Case X.—Female, married, aged twenty-eight, chancre of upper lip. Her husband was dissipated and was suffering from a sore throat. Contagion by kissing. Enlarged glands and eruption substantiated the diagnosis.

Case XI.—Male, married, aged thirty. Contracted chancre from a prostitute who was suffering from sore throat. Inoculated his wife with chancre of the lip.

Case XII.—Female, cook, aged twenty, complained of a sore on her lip. The family had been away in the country during the summer, and she had entertained a male companion whom she was engaged to marry. Enlarged glands, eruption. Diagnosis, chancre. She caught the sore by kissing her lover, who was suffering from mucous patches of the lips and tongue. The diagnosis was made none too early in this case, as there were two babies in the family that the cook would fondle and kiss. The disease was not transmitted.

In looking over these cases and their histories it can be seen that chancre of the mouth, although not such a common disease, does exist; and knowing how readily the mucous patch of the mouth will inoculate a chancre it seems strange that there are not more cases of the primary lesion occurring in this locality reported.

It is interesting also to inquire into the occupations of some of these syphilitics. One patient, where I removed all the turbinated bones and septum in a necrosed condition made biscuits in one of the largest cracker houses in this city. The inside of his nose was one large ulcer, and the smell from the part indescribable.

One of the cases of chancre I have reported made pencils. No one would hesitate to put a pencil in the mouth to moisten the lead, yet here was a syphilitic who

handled them and who was liable to transmit some of the virus through these agents.

I have treated any number of syphilitics suffering from mucous patches who made cigars. Cooks who served in families and tasted the soups have applied to me, at the Bellevue clinic, for treatment for mucous patches.

Some of these cases do transmit their disease, while all suffering from the mucous patch of the mouth are liable to transmit the chancre virus to some innocent party.

We have a Board of Health to whom we are compelled to report all our cases of measles, scarlet fever, diphtheria, and kindred diseases; but a patient suffering from mucous patches or chancre of the body is allowed to roam at large, dispersing his contagion to any unfortunate, whether the innocent be a baby, child, or adult.

A law should be passed making the examination of the buccal cavity compulsory in all factories where the article of manufacture is liable to carry any syphilitic poison. This examination could be made at certain intervals, and the spread of this disease curtailed.

It is a dirty disease, it is said, so, like the ostrich when he is in trouble, the authorities hide their heads in the bushes and imagine everything secure.

112 West Forty-fifth Street.

A CASE OF POST-PARTUM HEMORRHAGE FOLLOWED BY SEPSIS—TREATMENT OF THE ACUTE ANÆMIA BY SUBCUTANEOUS INJECTIONS OF A SALINE SOLUTION—RECOVERY.

By B. ONUF-ONUFROWICZ, M.D.,

DOLGEVILLE, N. Y.

On February 24th I was called to see a patient who was in a state of great weakness and extremely anæmic from post-partum hemorrhage. The patient had had four normal confinements; all children were born at term and are alive to-day. No miscarriages had occurred previously. The menstruation had been regular and normal in quantity.

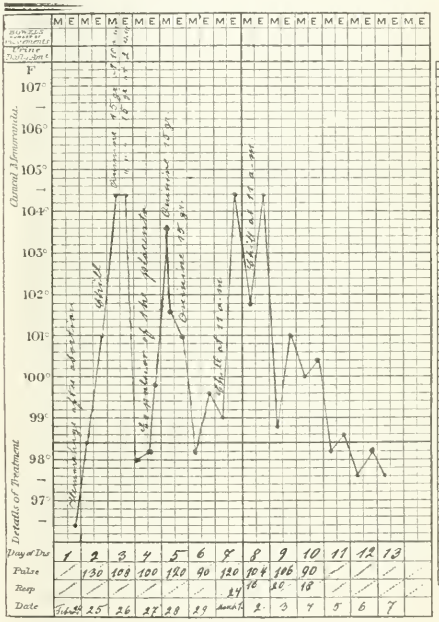
About December 22, 1891 (the exact date could not be traced), she had normal menstruation, or at least thought she had. Four weeks afterward, when she again expected it, she lost but a few drops of blood. She felt well, with the exception of a strong desire for well-seasoned and sour food, such as herrings, sauerkraut, etc.

It was, so far as the patient remembers, on February 14th that she had a rather considerable loss of blood from the vagina, which was caused by a fall on the floor. The hemorrhage lasted three days. Afterward she felt quite well until the evening of February 23d, when she became somewhat chilly. During the following night labor came on, and on February 24th, at 5 A.M., the fœtus was born, and with it an enormous quantity of blood was discharged. Blood continued to flow until 2 P.M., when I was first called to see her. The quantity of blood she had lost could not be stated exactly; a certain estimate was possible from the fact that it had soaked through the thickness of two mattresses and gathered in a large pool on the floor beneath. I should judge that she must have lost at least two quarts of blood. As she was rather anæmic before the hemorrhage occurred, and was not a robust person, this was a very serious matter.

When I arrived, I found the woman deathly pale, with hardly perceptible pulse. She complained of a peculiar oppression in the region of the heart, of nausea and dizziness. The slighest movement of her head caused everything apparently to turn around her. When she closed her eyes she had the sensation as if her entire body were dead. She was still losing blood constantly, although it flowed but slowly.

After I had irrigated the vagina with a one per cent. solution of salicylate of soda, I disinfected my hands thoroughly and made a vaginal examination. I found the uterus rather soft. The cervix was dilated sufficiently to let two fingers pass in easily. I could feel the placenta as a very soft, pulpy mass adhering to the walls of the uterus. I first tried to loosen the placenta, but soon gave it up, as I felt satisfied that this would be impossible without injuring the walls of the uterus and tearing the pulpy placenta to pieces. Thereby I would have risked leaving detached pieces of it in the uterus. But as the blood was still flowing immediate action was required. I therefore wiped the uterine cavity out with a piece of aseptic gauze soaked in turpentine, and tried to stimulate the organ into contraction by Credé's method. When by this procedure the hemorrhage ceased, the general condition of the patient required my fullest attention.

I first injected into the rectum one quart of a 0.7 per cent. watery solution of chloride of soda, to which two ounces of whiskey had been added. (I wish to state here in advance that all the water was absorbed.) Then I made everything ready for infusing a saline solution into the femoral artery according to the method of Dr. Dawbarn.[1] This method impressed me by its apparent sim-



plicity, which seems to enable the general practitioner to perform it almost at any time, as the apparatus required, viz., a Davidson or fountain syringe, a soft rubber catheter, and a hypodermic syringe, are usually at hand, and as the technique seems to be very simple. I am sorry to confess that, in spite of this, I did not succeed in my attempt.

After I had made the connection between the Davidson syringe and the catheter, which both had been thoroughly disinfected, I pushed the needle of a hypodermic syringe into the skin below Poupart's ligament, just where I could feel the pulsation of the right femoral artery. To have the least blood-pressure to work against, I directed the needle with its point toward the foot, keeping it at an angle of about sixty degrees with the axis of the thigh. My first attempt was a failure, as no blood came out of the needle. I took the needle out and tried for the second time, again without success. The panniculus adiposus of the patient (though she could not be called a fat person) was rather strongly developed. Perhaps this was the cause of my failing to strike the artery; I suspect that I did not introduce the needle deep enough.

[1] Medical Record, vol. xli., No. 1, page 1.

But whatever may have been the cause, I made no further trials, and resolved to inject the fluid into the subcutaneous cellular tissue.

For this purpose I connected the needle of the hypodermic syringe with the catheter, which at its other end was connected with the Davidson syringe. I chose the skin of the upper thighs as a suitable location for the infusion. I introduced the needle into the subcutaneous cellular tissue, and injected the solution (sod. chloride, 7 parts; water, 1,000 parts), which was kept as hot as the hand could bear, until a rather tense tumor had formed on the surface. Then I took the needle out and repeated the procedure in another place. The injection was made in about ten different places on both upper thighs. I ceased to inject when a little more than one pint of the solution had entered the subcutaneous cellular tissue. The salt-water was promptly absorbed, since in the course of six hours the swellings produced by the injection had entirely disappeared.

The general condition of the patient had improved during the injection, which had lasted about half an hour. The pulse had become fuller, the feeling of oppression and both the nausea and dizziness had diminished, and her face had regained some color. I found that the immediate danger had passed.

Judging from my experience in this case, I should think that one quart of fluid, or even more, could be easily introduced into the subcutaneous cellular tissue. In a case of urgency, however, I should prefer the infusion into the artery, and I hope that in the future I shall be more successful in accomplishing it.

After I had examined through the abdominal walls, I found the uterus well contracted and no blood flowing. I then examined the fœtus. I found it completely enveloped in a mass of coagulated blood; it was soft and pulpy, evidently by maceration, but it was still sufficiently preserved to allow an estimate of its age. It was three inches long, and had the appearance of a fœtus at the end of the fourth or beginning of the fifth month. Accordingly the patient must have mistaken uterine hemorrhages during the pregnancy for menstruations. Of both placenta and membranes nothing could be found among the blood clots expelled.

At 8 P.M. I saw the patient again. Her general condition was satisfactory. She still felt oppressed and dizzy, but less so than before. She had the sensation as if her left arm was dead. Pulse pretty good, about 120. Temperature, 96.4° F. I again irrigated the vagina with a one per cent. solution of salicylate of soda, and injected a pint and a half of water into the rectum. This water was partly absorbed and partly expelled.

On February 25th the patient complains of headache and of pain in the various spots where the saline solution had been injected subcutaneously. The feeling of oppression has nearly disappeared. She feels very thirsty. No loss of blood. Uterus rather well contracted. Toward evening the patient felt chilly and her temperature rose to 101° F. I gave two grains of calomel, as her bowels had not moved for several days. Irrigation of the vagina with a one per cent. solution of salicylate of soda t.i.d.

February 26th, A.M.—The patient has had four evacuations of the bowels since yesterday. The pain where the subcutaneous injections had been made is nearly gone. She still complains of headache. The temperature has risen steadily since when it was first taken; it has reached 104.4° F. at 11 A.M. I ordered quinine, fifteen grains. At 2 P.M. the temperature is still 104.4° F., so the same dose of quinine was given again. In the afternoon a considerable quantity of coagulated and liquid blood is passed per vaginam. The patient receives fifteen grains of fluid extract of ergot, subcutaneously, and the uterine cavity is irrigated with a one per cent. solution of creoline. This irrigation produces violent pain, and morphine has to be given subcutaneously to relieve it. In the evening the patient complains of nausea, but has no pain. The hemorrhage, which was promptly checked by the ergot, has not returned. The temperature has come down to 98.2° F. at night.

February 27th.—The patient slept well during the night. She has but little nausea. Fifteen grains of the fluid extract of ergot are given again hypodermatically, in the forenoon. At noon the placenta is expelled. It is a soft, pulpy mass, which is infiltrated with pus and has a most offensively foul smell. Accordingly, the lochiæ smell very foul too. Irrigation of the uterus with a sod. salicyl. solution after the expulsion of the placenta, which irrigation is repeated at night.

February 28th.—The odor of the lochiæ is much less offensive than it was yesterday. Severe headache. Pain in the left arm and leg, chiefly in the elbow-joint. There is no redness nor swelling. Tongue somewhat coated. Appetite rather poor. The temperature has been rising steadily since yesterday noon; it reached 103.3° F. this forenoon, and went down to 101.6° F. in the evening. Ordered quinine, thirty grains, in two doses. Irrigation of the vagina with sod. salicyl. solution twice. Castor-oil as a laxative.

February 29th.—Pain in the left arm and leg less severe. Intense headache, which is highly increased by the slightest movement of the head. Temperature, 98.2° F. in the morning, 99.6° F. in the evening. Ordered morphine internally to relieve the headache, which is the most prominent symptom.

March 1st.—The condition of the patient is the following: She looks very anæmic; lips somewhat bluish; skin rather dry. Skin and conjunctivæ have yellowish hue, the latter especially, where covered by the lids. The breasts are flabby and of somewhat dark color; a colostrum like liquid can be pressed out of them. Body and extremities free from swellings. No meteorism. The tongue, which showed a thick coat the day before, looks much cleaner to-day, but shows some fissures. Lungs free. Twenty-four respirations per minute. Heart-sounds quite distinct. The second sound is somewhat prolonged. Action of the heart regular. Pulse rather full, regular, 120 beats per minute. There is some enlargement of the spleen, the dulness in its long diameter being somewhat increased from above downward, say seven finger breadths in one and five in the other direction. The percussion-sound is almost flat. Edge of the spleen distinctly palpable. The cervix is considerably swollen and admits two fingers easily. No infiltration of the parametrium or peritoneum. The lochial discharge has nearly lost its odor. Pain in the right elbow and knee more intense. The patient has also pain in the right shoulder-joint, and the sensation as if cold water was poured on these joints. On inspection no redness, no swelling is visible, but there is some sensitiveness to pressure. At 11 A.M., soon after the examination was made, the patient had a chill. The temperature, which was 99° F. in the morning, rose to 104.4° F. in the evening. No antipyretics were used. The patient got some moderately strong wine and fluid food, such as milk, raw or soft-boiled eggs, beef-tea, etc. Morphine to relieve the headache.

March 2d.—Has still pain in the left arm and leg, and also in the abdomen. The temperature has fallen to 101.8° F. At 11 A.M. the patient has a chill, and in the evening the temperature reaches again 104.4° F.

March 3d.—The pain in the abdomen has disappeared after the administration of one tablespoonful of castor-oil. The headache has diminished; the head aches only when the patient moves it. In the left arm and leg she has now no real pain but the sensation of pricking, which appears only at times. Temperature, 98.8° F. in the forenoon, 101° F. in the evening.

March 4th.—The patient is in much better spirits, inclined to joke, and believes that she would be perfectly healthy if the headache had entirely left her. Temperature, 100° F. in the forenoon, 100.4° F. in the evening.

March 8th.—Since March 5th the temperature has not

exceeded 98.6° F. The patient is still rather weak, has some headache, but feels well otherwise.

March 22d.—Has been out of bed for the last few days. The headache is gone, but she still feels dizzy at times. No pain in the back, no retention of the urine, very little discharge from the vagina, fair appetite. The patient has recovered so far that she can be safely discharged. I wish to add here, that during the whole course of disease the function of the bladder was normal, or nearly normal, and that there was no excessive secretion of sweat at any period of the disease.

To sum up, the predominant features of the case were the following:

1. The course of the temperature, as shown in the table, is characterized by three typical chills and by the irregularity of the curve, which repeatedly ascends very suddenly and descends just as suddenly and steeply. Partly, however, the type is masked by the quinine given in the beginning of the disease.
2. The slight icterus which was present.
3. The enlargement of the spleen.
4. The pain in the joints characterized by the want of any objective sign.
5. The violent headache.

The case was one of sepsis in which the general symptoms of infection prevailed. The course of the temperature was similar to that observed in cases of tropical malaria, which the disease resembled in many other points. The etiology, however, leaves no doubt as to the nature of the case in question.

Cases of septicæmia do not occur frequently in this period of antiseptic treatment. I, therefore, concluded to publish this case, although I make myself liable to be accused of having neglected the proper use of antiseptics.

In my defence I may state that the circumstances under which I had to act were most unfavorable. The fœtus had probably been dead for several days or weeks before it was born. The placenta was decomposed. The surroundings of the patient, especially the clothes and linen with which she came in contact, were exceedingly unclean. Rapid action was necessary, as the life of the patient was in danger, and though my hands and the instruments used and the genitals of the patient were treated strictly antiseptically, a complete asepsis could not be attained under the circumstances mentioned. Finally, the woman was very much predisposed to the invasion of microbes in consequence of the weakness, which resulted from the hemorrhage.

The Disadvantages of English Sanitoria.—Dr. A. Tucker Wise, in his work on the "Alpine Winter in its Medical Aspects," intimates that the reason why the treatment of incipient phthisis in the south of England resorts is so unsatisfactory, and why so much better results are obtained in Continental sanitoria, is that in the former little or no attention is paid to the requirements for comfort and health of the visitors. "In addition to the rain and wind of the British Isles," he says, "there appears to be also either a total ignorance or disregard of the requirements of health visitors There are scarcely any shelters provided—no glass covered galleries, verandas, nor convenience for taking the air in wet weather. Indoors, the temperature maintained by stoves and open fires is most uncertain and partial. If any ventilation is available it is by Tobin's tubes, or apertures communicating direct with the exterior, quite unsuitable for a windy climate. I have seen 'through' ventilation adopted for corridors—an excellent system in hot weather, but unbearable and perilous in our English winter. These drawbacks alone drive hundreds of English people to seek change in other countries in spite of the disadvantages entailed by travel or absence from home and friends."

The Druggists in Saratoff, Russia, have agreed to supply poor people with drugs free of charge up to the amount of $100 per annum for each druggist.

Clinical Department.

A CASE OF FRACTURE OF THE PENIS.

By ALBERT KROG, M.D.,

NEW YORK.

Although such a condition as the above cannot possibly exist, I have nevertheless retained the term in order to signify the lesion as generally understood, but meaning simply and purely a contusion and laceration of the organ. The case, which I have been but lately able to observe, is worthy of record in consequence of its rarity.

N. N——, a Swede of powerful physique and health, called upon me to ask advice regarding the peculiar condition of his penis. Eight days previous to my seeing him he got up in the middle of the night on account of not being able to sleep, and looked out of the window. Suddenly the window came down with a tremendous force and struck his penis a little behind its middle portion. Thus far *his* history.

Soon after the organ began to swell immensely, and for the next three days blood oozed from the urethral canal. Besides the swelling, there was considerable discoloration. At the time of my seeing the patient, eight days after the accident, the organ was pendulous, swollen six to eight times its normal size, and of purplish-blue color. There was no pain whatsoever, urine passed slowly but without any trouble. From the fact that blood had oozed from the canal for several days, I surmised that the corpus cavernosum had been lacerated, and with it also the mucous membrane of the urethra. The patient would not allow me to pass a catheter. I ordered simply a lotion of lead-water. No doubt my patient had been the subject of a chordee, and had himself thrown the window upon the organ in order to get rid of the unpleasant condition.

From the few cases on record, there seems to be but little trouble as to the absorption of the hæmatoma. The great danger lies in the rupture of the urethral canal and its consequent absorption of bacteria. Death may occur as the result of pyæmia and gangrene. The cicatrix formed, generally produces a curvature and malposition of the penis. The part anterior to the lesion is necessarily deprived of the possibility of erection. In case of sloughing (abscess) of the integument of the penis, high fever usually occurs.

Treatment consists in the application of cold, in the form of water, ice, ice-bags, lead-water, etc., rest, and support of the organ upon the abdomen. In case of abscess and infiltration of urine, incisions are necessary. The catheter should be frequently used, or even retained permanently.

221 East Tenth Street.

TRANSPOSITION OF THE VISCERA.

By IRA T. JOHNSON, M.D.,

ROCHESTER, N. Y.

Mrs. M. E. B——, aged forty-nine, died of uterine cancer, April 23d last, and for certain reasons the coroner ordered an autopsy, which I, as coroner's physician, performed the next day. I found the following rare arrangement of the internal organs:

The right lung had two lobes, and the left lung three.

The heart was on the right side of the spinal column, occupying the same position relatively that it should have on the left side.

The arch of aorta turned to the right, and the thoracic portion descended on the right side of the median line. The innominate arose from the left side of the arch, and the common carotid and subclavian from the right side.

The position of stomach was reversed, the cardiac end lying to the right of the median line, and the pyloric end to the left. The position of the several portions of intestine was the reverse of the usual.

The spleen was on the right side, and the liver on the left.

The vermiform appendix occupied the same relative position on the left side that it should have occupied on the right.

In fact, it was a case of complete transposition of all the internal organs, though the ureters, kidneys, and some other parts which would require a more thorough investigation to determine whether they were transposed or not, were not examined as closely as they should have been with regard to that point. The woman had always been right-handed.

Physical examination of a daughter aged sixteen years, and of similar disposition and appearance as the mother, did not disclose any abnormal position of the internal organs.

A NEEDLE IN THE OVARY.

By FRANK W. HAVILAND, M.D.,

NEW YORK.

Mrs. S. C——, aged twenty-one; married four years; has never been pregnant. She has been complaining of abdominal pain and tenderness, and has had a bloody flow from the vagina for about two months. On July 1, 1892, an examination was made and a diagnosis of pelvic neoplasm requiring operation was arrived at. On July 16th, assisted by Drs. Ludden, McCready, and McCroskey, the patient being under ether, I made an incision in the median line, and directly under it found a large irregular mass, on either side of which could be felt a smaller mass, all bound firmly together and to the floor and sides of the pelvis. On attempting to raise the omentum I found it bound firmly to the central mass, and much inflamed and thickened. It was torn loose, and while this was being done a small abscess was ruptured, allowing pus to enter the abdominal cavity. After thoroughly washing out the peritoneal cavity with hot water, the large, thick, and inflamed portion of omentum was ligated and removed. The uterus could now be felt, with the upper portion of the sigmoid flexure firmly united to the upper portion of its posterior wall, and all bound down by firm adhesions. After ligating and cutting through the larger bands, and tearing through many others, the gut was successfully separated from the uterus, leaving the wall of this organ much torn and bleeding. The hemorrhage would not yield to the cautery nor to pure carbolic acid, but was controlled with a deep stitch of catgut firmly tied. The small mass on the left side was now torn from the floor of the pelvis, and was found to be an ovary and tube much thickened and inflamed. This was ligated and removed. The mass on the right side was raised, after cutting and tearing through adhesions, and found to be an ovary and tube forming a mass about the size of a duck's egg. The mass was ligated and removed. The abdominal cavity was now thoroughly washed out with hot water and closed with interrupted sutures of silk-worm gut.

The day following the operation the diseased tissues were carefully examined. The large mass taken from the right side, presenting a large fluctuating surface, was incised, and a quantity of pus escaped. To ascertain the extent of this abscess cavity I inserted my index-finger, which received a sharp prick. On turning to the light and examining further, I found a portion of an ordinary sewing needle, about three-quarters of an inch in length, very much discolored, and with a sharp point.

It is more than probable that this portion of the needle had been swallowed by the patient, passed through the alimentary canal to the sigmoid flexure, where it penetrated the wall of the gut, passed on through a fold of the omentum and into the peritoneal covering of the posterior wall of the uterus, and finally into the right ovary. It carried with it infection from the alimentary canal which produced an inflammation along the whole course traversed by the needle, thus causing the gut, omentum, and uterus to be firmly bound together by inflammatory products, and the ovarian tissue to break down.

The patient recovered from the operation without complications, and since July 30th has been about the house, feeling better than for many months past.

THE NERVOUS SEQUELÆ OF TYPHOID FEVER.

By R. ELLIS, M.D.,

DANBURY, CONN.

The nervous sequelæ of typhoid are many—embracing lesions of the meninges, brain, spinal cord, spinal, and peripheral nerves.

In this fever a practitioner expects every complication, and he is surprised at no nervous sequelæ. In the meninges we may observe the following lesions: purulent inflammation, congestion, minute hemorrhages, œdema, cerebro-spinal meningitis. In the brain itself we may meet with cerebral hemorrhage, thrombosis, embolism, and congestion. The nervous lesions are shown by their characteristic physical signs, due to central or peripheral causes, such as hemiplegia, paraplegia, anæsthesia, hyperæsthesia, convulsions, local paralysis, aphasia, and neuralgia. Hemiplegia is rarely seen, and recovery usually follows. Paraplegia (cervical to lumbar) very rarely occurs, and recovery seldom follows. Extreme nervous exhaustion may bring on a complete hemiplegia or a paraplegia, with slow recovery. If, however, a post-mortem follows, one need not be surprised to find no cause to explain the evident lesion—the cause lies in the exhausted vitality of the nerve-cells.

In my practice last winter a young man (twenty-three), ill twenty days with the typhoid fever, developed complete sixth cervical paraplegia with almost complete anæsthesia, and died in two days. No autopsy was allowed, but I felt convinced that no pathological condition existed sufficient to explain the complete paraplegia, save anæmia and exhaustion of the spinal cord.

Anæsthesia is often observed. Hyperæsthesia, general or local, is, however, by far the most common of all the nervous phenomena observed in this fever. This hyperæsthesia may occur during any stage of the disease, and is often of very serious annoyance. I remember a case occurring in the fifth week (patient convalescing), when the hyperæsthesia, limited to the toes of the right foot, was so severe, especially at night, as to require hypodermics of morphia and a cradle to keep all clothing from touching the sensitive area. So persistent and annoying was this hyperæsthesia that the patient's life was endangered, and finally it became necessary to remove the sufferer from college to his home—a distance of one hundred miles. Though the weather was intensely cold, the patient was benefited by the trip, and rapidly recovered from his severe attacks, but weeks elapsed before perfect recovery—weeks during which, at intervals of twelve to twenty hours, the patient would be suddenly seized with intense hyperæsthesia of the big toe. It seems necessary to say that hysteria did not increase the hyperæsthesia, for the patient was a college man of strong physique.

Convulsions with opisthotonos are rarely observed, and are usually due to a previously existing kidney lesion, increased by pathological renal and blood changes.

Some form of local paralysis is frequently noted—paralysis embracing all or a single one of the muscles related to the part. An entire extremity may be paralyzed, but often only a single muscle or a group of muscles—as the flexors or extensors, or a group supplied by a single nerve, as the musculo-spiral group.

Aphasia, amnesic or ataxic, occurs, and is usually complete—slow recovery follows, as a rule.

Neuralgia is very common, especially of the head, face, and trunk.

Toothache is often so severe as to greatly distress the patient.

Peripheral neuritis occurs—neuritis characterized by pain and swelling, and so differentiated from local hyperæsthesia in which swelling does not take place.

Multiple neuritis and poliomyelitis occur but rarely. Both may present the same symptoms, but the paralysis from poliomyelitis is persistent, and muscular anæmia and weakness continue, whereas in multiple neuritis the symptoms may, in a short time, entirely abate.

Insanity, due to cerebral malnutrition, is usually of short duration—the intelligence returning slowly as strength is gained.

The system is so exhausted as the fever develops and convalescence follows that as a result of nervous depression we may at times find signs of central nervous injury. In these cases it is well for the practitioner to avoid a too hasty diagnosis of organic nerve lesion, for these nervous symptoms of organic lesion ofttimes quickly disappear. I remember a case of hemiplegia in a young lad where all the symptoms pointed to a poliomyelitis, and for this reason a prognosis unfavorable as to a complete recovery was given. Yet after the patient gained strength and could take solid food, the paralysis entirely disappeared.

EYES OF DIFFERENT COLOR.

Dr. Joseph Forrester, of Butler, Pa., writes that Dr. Hubbel's observation, published in a recent number of the Medical Record, has been duplicated by himself. He says:

"My case is a girl aged eight, a blonde, except the iris of one eye (the left, I believe), which is hazel, but somewhat irregularly pigmented, while the iris of the right is a clear blue. Her father is a blonde, with blue eyes and very light-colored hair, eyebrows, eyelashes, and beard. The mother is a handsome brunette with dark brown hair and hazel eyes. Both parents are young and the girl is their first child. The family lives in Salamanca, N. Y.

QUININE IN CHOLERA.

By ERSKINE B. FULLERTON, A.M., M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, STARLING MEDICAL COLLEGE, COLUMBUS, O.

In Dr. John M Woodworth's "Cholera Epidemic of 1873 in the United States," under the head of "Notes on Treatment," quinine is referred to as having been given in small doses, at uncertain intervals, by two writers, and by one in conjunction with atropine, amounts not stated.

In Dr. Edward O. Shakespeare's "Report on Cholera in Europe and India" no reference is made to quinine in the chapter in which treatment is considered, but it was used in the cities of Teruel, Toledo, and Tembleque in Spain during 1884. The dose is not mentioned in any case, nor the method, except in one only, where it was the hypodermic, with a strong inference that it was so used in the two other cities. The journals at the time gave the dose as fifteen grains, administered hypodermatically. When we recall two well-known facts—first, that the Koch germ is found inside the intestine and not in the blood, and secondly, that the direction of quinine is toward the kidneys, but little, under ordinary circumstances, escaping with the fæces—a reason for failure when administered hypodermatically is apparent. In 1884 Koch places quinine next to mercuric chloride in development-inhibiting (not disinfectant) power, the former acting in strength of 1 to 5,000, the latter in that of 1 to 100,000. In other words, one-half grain of the mercurial is the required equivalent for growth-inhibition of ten grains of quinine. When it is recollected that the lethal dose of the one is about two grains, and that of the other about two ounces, the disparity for practical effects is apparent. If five grains of quinine can inhibit the development of the spirillum in three pints of rice-water discharge *in situ*, what ill effect can be apprehended from four or six times that amount? All this, however, is "reasoning after the event" with the writer.

In the epidemic of 1873 the use of quinine was early begun in cases coming under my care in this city. In over thirty cases of choleraic diarrhœa there was only one that proved refractory to the quinine treatment, developing into what under the old nomenclature would be called a mild case of cholera. Of the severer or typical form of the disease I had five cases, in all of which quinine was given in doses of seven and one-half grains in solution in the usual way, by means of a sufficient quantity of aromatic sulphuric acid; and this dose was repeated at intervals of an hour and a half until the symptoms were under control, then in smaller doses at longer intervals. Ice was allowed from the first in guarded quantities, and, so soon as the tendency to vomit was sufficiently controlled, ice-water.

In some cases a small amount of morphine was given, in others not. In all cases there was decided improvement after the first dose, and a steady abatement of the symptoms as the treatment progressed. The patient in whom the disease was, perhaps, farthest advanced when treatment was commenced vomited but three times and purged but twice after the first dose was given. In this case, with the typical pulse, thirst, cramps in extremities, sunken countenance, and loss of voice, the vomiting was incessant, and the constant discharge from the bowels had penetrated the mattress and stood in a pool on the floor beneath. In one case in which I was consulted by the physician in attendance, quinine was exhibited to the extent of fourteen grains in the pill form. The patient's symptoms, typical as described, were controlled for forty-eight hours, he returning to his place of business on the second day. At the end of the above-mentioned period the symptoms returned and he died in the course of a few hours, no quinine having been administered during the relapse.

While aware of the danger in forming conclusions too radical on the success of treatment in so limited a number of cases, and also bearing in mind that epidemic diseases differ in tractability and severity during different seasons of their prevalence, and at differing periods of the same epidemic, yet I have been unable to rid my mind of the impression, strongly made nineteen years ago, that the quinine treatment had much to do with the results above recorded. That the disease prevalent in Columbus, O., in 1873 was of no mild type is shown by the report of Dr. Woodworth, where, out of one hundred and thirty cases recorded, there were ninety deaths, a mortality of more than sixty five per cent.

Permit me to strongly urge upon the physicians now treating the disease in quarantine or hospital that they try the remedy. I would suggest that one drachm be dissolved in three ounces of water by means of a sufficient quantity of dilute or aromatic sulphuric acid, and that of this solution a tablespoonful be administered and at once repeated if vomiting occurs, and afterward at intervals of an hour and a half, until thirty grains have been taken, and thereafter pro re nata. If judged best, a small amount of morphine may be added, or a few drops of chlorodyne—their utility I doubt. There are a few provisos:

1st. The ten-grain doses should be in solution, so that in case of vomiting some may be retained.

2d. That the patient be not already moribund from toxæmia, or in pulseless collapse.

While the discoveries of the last few years render the theory of Dr. Cunningham, that cholera is "malaria perniciosa," untenable, there is nothing as yet by which we may infer that the treatment may not be essentially the same.

Eggs by Enema.—Dr. Huber says that the absorption of eggs administered in enema is markedly promoted by the addition of about fifteen grains of salt to each egg. Peptonizing the eggs also increases the chances of their absorption by the rectum.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, October 1, 1892.

MODERN TREATMENT OF CHOREA.

CHOREA, a disease so called, is better described as a chain of symptoms belonging to some disorder of which the pathology is at present unknown. This symptom group embraces irregular spasmodic movements, incoordination of voluntary motion, and often muscular and mental weakness.

The mental impairment may become a real insanity. The forms of mental abnormity most common in chorea are mania and delirium, running into chronic delusional states, and sometimes ending in dementia. Whatever the disease or diseases now known by the generic term chorea may really be, the condition is in itself sufficiently serious to demand the best skill and care of every conscientious practitioner. Better methods to secure more rapid results are what everyone is looking for, in spite of the fact that ordinary chorea tends to disappear, whatever the treatment, in from eight to twelve weeks. In the *International Medical Magazine*, July, 1892, James Hendrie Lloyd states that most of the benefits obtained by treatment are obtained by attention to the condition of the blood Hence arsenic and iron are the best drugs.

Chorea as seen and treated in Parisian hospitals offers some points of special interest.

The *University Medical Magazine*, June, 1892, contains a valuable abstract of French opinions concerning the treatment of this disorder, collected by Marcel Beaudoin and published in the *Revue de Thérapeutique Medico-Chirurgicale*, April 1, 1892.

While antipyrine is considered valuable by the majority of physicians interviewed, the views held are widely different, and seem in their diversity almost as much an affair of temperament as of experience. They afford a refreshing change, however, from the provincial routine that prevails in too many cis-Atlantic dispensaries. Among Parisian doctors, at least, Fowler's solution is not the great and only remedy. One, Dejerine, insists that all special medication in infantile chorea is useless. Tonics, massage, gymnastic exercises, dry frictions, salt baths, and general sound hygienic measures are earnestly recommended. Massage, according to Ollivier, gives the happiest results. As internal remedies this practitioner prescribes iron and arsenic, and also makes use of hydrotherapy. Gilbert Ballet believes that common chorea tends to spontaneous cure, and that disturbing drugs should be withheld. Antipyrine he condemns though believing in Fowler's solution in small doses, and in tonics and iron for anæmic cases. The local application of ether to the vertebral column is recommended when the disease assumes a serious form, and bromide of potassium when there is mental disturbance. Strict hygiene, good food, walking in the open air, avoiding all fatigue, Ballet considers essentials of treatment.

Jules Simon, earlier on record as realizing the harm ; residence at the sea-shore may do to sick children, condemns it in chorea. The least exciting tonics, as salt baths and dry frictions, he advocates, together with the following general plan of treatment : 1. During the first fifteen days the child is to lie in bed, and warm frictions mustard-plasters, or dry cupping are to be applied over the upper part of the back, hemlock and aconite being the internal remedies. 2. At the end of a fortnight the child is allowed to get up, and antipyrin is administered in progressive doses of one, two, three, four, and five grammes in the course of twenty-four hours. The drug is thus given for several weeks. 3. Then arrives the time for rhythmical gymnastics, especially necessary when bodily movement is sluggish. Legroux, Raymond, Sevestre, and Albert Robin think highly of antipyrin. The latter combines it with bicarbonate of soda, and gives it in as high a dose as two grammes a day. After a fortnight's use of antipyrin, the arseniate of sodium is substituted, in doses of two teaspoonfuls daily of a solution of five centigrammes to three hundred grammes of water This solution finished, antipyrin is again administered Moral psychic hygiene Comby considers of first importance, then quieting of the nervous system by bromide of potassium in daily doses of from two to four grammes together with cold douches.

Should this treatment fail, antipyrin is given. In ordinary cases, Germain Sée recommends arsenic and antipyrin. Rheumatic subjects require salicylate of sodium, associated with antipyrin and sulphur baths. In cardiac choreas this authority advises the addition of iodide of potassium and iodide of calcium to the heart remedies. Prolonged sleep, induced by chloral if necessary, Joffroy considers all important, especially in mild cases. Fatigue, as well as physical and mental excitement, must be strenuously avoided.

Hypnotism, so much in evidence of late, has also been tried as a remedy for chorea. In *Normandie Médicale*, August 1, 1892, Gibert, of Havre, reports amelioration of grave symptoms in a girl twelve years old, by means of hypnotic suggestion. Will training, rather than hypnotism, more nearly expresses his method. Bromide of potassium, gymnastics, hydrotherapy, had proved equally without avail. Night and day the inco-ordinated movements of general chorea never ceased. A fortnight of carefully graded commands and some massage of the facial muscles brought about wonderful improvement, sleep became natural, and the girl's countenance regained an expression of intelligence. The patient then could restrain all choreic movements in the presence of the physician when ordered by him to keep perfectly still ; but when away, a mild chorea still remained. A residence in the country, far from all relatives, among hardy peasants, who were directed to ignore the child's condition, brought about a perfect cure. The author called

ttention to the fact that there are purely neurotic horeas, such as Luys claims to cure by means of revolving mirrors, and that this form of the disease is commoner than any other. Fever and heart trouble in horea can be explained on other grounds than rheumatism. They denote profound disorder of innervation, often existing as manifestations of hysteria in children, nd are in no sense due to rheumatic poison. As no art of the human economy requires so much oxygen as he nerves, the imperative necessity of country life in the reatment of chorea is at once apparent.

PREVENTIVE INOCULATIONS AGAINST CHOLERA.

THERE has been a good deal written and said in regard o anti-choleraic vaccinations, and the subject is naturally ne that excites much interest. While it is very unlikely hat cholera will ever be best dealt with by any process f "vaccination," yet the discovery of some practical nethod of securing immunity would be of great service. n Berlin, Brieger, Kitasato, and Wassermann have made esearches which show that some of the lower animals an be protected against inoculations that in control aninals cause cholera. The immunizing liquid was obained by cultivating the microbe in a solution of tissue ibrinogen.

The experiments have been carried much further by Haffkine, of Paris, working at the Pasteur Institute. His investigations have been unfortunately attended with a great deal of newspaper notoriety, which we believe ould not have been sought for or desired by the investigator. In the *British Meaical Journal* for September 10th, Mr. E. H. Hankin, who has been subjected personally to Haffkine's inoculations, gives an account of he new method.

The first step in getting a protective vaccine was to produce an abnormally virulent culture of the cholera microbe. This was done by passing the virus through a series of guinea-pigs. By adopting a special process it was found that the virus increased in intensity until a maximum was reached. The *virus fixe* thus obtained kills the guinea-pig in six to eight hours, whether given per os or injected into the peritoneum. If injected under the skin, however, it produces only a local inflammation and necrosis, and if the animal recovers he is found to have immunity. Since the local disturbance and necrosis are serious, however, it was found necessary to prevent this, and to this end the *virus fixe* is attenuated by growing the microbe in a slow current of air

If a dose of this attenuated virus is injected under the skin of a guinea pig, an extensive œdema develops within twenty-four hours. During the next few days this diminishes in size, leaving, however, a hard nodule, which persists for a considerable time. If a week later the animal is inoculated with a similar quantity of the strengthened virus, an œdema develops, which is less than in the first case and does not lead to necrosis. When tested a few days later the animal is found to have acquired an immunity against the cholera microbe in whatever way it may be inoculated. This immunity has been found to be undiminished a couple of months after treatment.

Rabbits have also been made immune by the same method. They then show themselves refractory to every form of inoculation, including the method above described, which in the control animals leads to a disease resembling the cholera of human beings. M. Haffkine has also produced this immunity in pigeons. These facts led M. Haffkine to try the effect of these inoculations on himself, and afterward on seven other gentlemen.

Two inoculations were given. The result was to produce a local œdema and swelling, with some fever and malaise. The local effects pass off, leaving only a hard nodule at the point of injection.

It is interesting to observe that M. Haffkine has followed almost exactly the same process in securing his "vaccine" that Pasteur has done in securing the protection virus of rabies.

The question now arises, Does the protection protect human beings. The fact is not demonstrated, and more experiments are needed. In the first place, there is some reason for believing that the same method which protects gninea-pigs and rabbits will protect man; still the argument is not a very strong one. M. Haffkine has shown, however, that his virus does give topical immunity to human beings. If a person, for example, is inoculated subcutaneously with active cholera microbes, there results a widespread œdematous swelling and redness which lasts for several days, leaving a hard nodule. The reaction is rather characteristic. In persons who have received the protective inoculations, no such reaction occurs. Hence, since topical immunity is given by the inoculations, it is inferred that there is a constitutional immunity also.

The experiences of an immunized newspaper reporter in a Hamburg cholera hospital have been paraded for business purposes, and it is not possible to base any scientific conclusions upon them. Apparently he was no more exposed to cholera than some physicians and nurses who have escaped. The proof will come perhaps to a person who dared to take into their intestines the *virus fixe*.

TROUBLE IN TEXAS.

WE have watched with a prayerful interest the development of medicine, medical societies, medical colleges, and medical journals in the great State of Texas. There has always been an elemental freshness and vigor about the Lone Star institutions which gave promise of great things. Their journals have been the reddest, their society meetings the most parliamentary, their medical ethics the most sensitive, and their controversies the stormiest of any of the subdivisions of this great republic. Out of this friction and ferment there have come interesting journals, alert colleges, active and original physicians, and a State Texas Medical Association. But there is trouble brewing now for this latter organization. The *Texas Health Journal*, an interesting periodical devoted to sanitation, a particularly unadulterated baking-powder, and other useful things, begins its July leader as follows:

"The ignorant, inhuman, and brutal conduct of the Judicial Council of the Texas State Medical Association, during its session held at Waco, Texas, April 28 to May 1, inclusive, 1891, has no parallel in the proceedings of medical societies; in fact, such a precedent cannot be

found in this nineteenth-century civilization; white-capism towers into temples of justice when compared with it; in fact the darkest dungeons of hell, compared to the deeds of that Council, are as flowery gardens and oriental castles. For this humiliating conduct the twelve men who constituted the alleged 'Judicial (?) Council,' have just received a rebuke from the American Medical Association that ought to not only cause the eternal blush of shame to mantle their cheeks, but sink deep into their hearts and take possession of their very souls—provided they are blessed with such psychological qualifications and attachments."

We have looked around to see what was the cause of this retributive piece of rhetoric; but are as yet a little uncertain. It seems, however, that our esteemed colleague is reinstated and that everything promises to be right, so far as the *Health Journal* goes; but "the keen lash of criticism" is to be applied to the Judicial Council and the State Association hereafter, *pro re nata*. The lash is whirled about in an ominous way, later on; "Dr. Q. C. S. skins the gang that dominates," "Gangrene of a once honored body," are some of the pithy expressions with which our injured critic attacks the great Texas organization. We trust that justice will reign in Texas, and with it peace and prosperity to the State Society and the Lone Star editor.

News of the Week.

The New York State Association of Railway Surgeons will hold its Second Annual Meeting at the Academy of Medicine, in this city, November 14, 1892. The profession is cordially invited.

The New Mexico Medical Society, which was from 1881 to 1885 known as the Las Vegas Medical Society, was incorporated in the latter year under its new name, and though its membership and usefulness spread throughout the Territory, it was only this year that its managers felt able to hold the first meeting elsewhere, namely, at Albuquerque, on September 14th and 15th. The meeting was chiefly devoted to business affairs of the Society, though, besides the address on "The History, Present Necessity, and Future of the Society," by the retiring President, Dr. F. H. Atkins, papers were read by Dr. W. G. Hope, of Albuquerque, on the question, "Is there Malaria in the Rio Grande Valley?" which elicited vigorous discussion; on "A Fatal Case of Appendicitis Caused by a Grape-Seed," by Dr. E. B. Shaw, Atchison, Topeka & Santa Fé Railroad Surgeon, of Las Vegas; on "A Newer Procedure in Perineal Section for Stricture," by Dr. W. R. Tipton, of Las Vegas; on "The Taos Valley as a Resort for Consumptives," by Dr. T. P. Martin, of Taos; "A Résumé on Recent Progress in Establishing Immunity by Bacterial Products," by Dr. F. H. Atkins, of East Las Vegas. The interests of the Society were greatly promoted and many new members added, the total number now reaching fifty. The new officers are: *President*, Dr. James H. Wroth, of Albuquerque; *Secretary*, Dr. Francis H. Atkins, of East Las Vegas; *Treasurer*, Dr. W. S. Harroun, of Santa Fé. On account of the central position of Albuquerque, the annual meetings will probably be held there for the next few years.

The Second Annual Meeting of the American Electro-therapeutical Association will be held at the Academy of Medicine, in this city, on October 4, 5, and 6, 1892. The sessions will be held at 9 A.M. and 3 P.M. An exhibition of electrical appliances will be given, and numerous entertainments are provided for the guests.

The Enthusiasm for Quarantine has reached a high pitch in New Orleans where one earnest medical gentleman advises that we quarantine the world, keep our bowels open, and trust in God.

Malpractice Suits have the peculiar quality of being able to propagate their own kind. A few months since the court at Albia, Ia., mulcted a Dr. Abegg in a considerable sum for alleged malpractice in setting a fractured limb. As a result the coming term of said court has four malpractice cases to consider, aggregating $30,000 damages.—*Medical Review.*

The San Francisco Therapeutical Society was organized in San Francisco, July 23, 1892. The following were elected officers: *President*, Dr. F. A. A. Belinge; *Vice-President*, Dr. J. W. Blake; *Treasurer*, Dr. J. R. Davidson; *Secretary*, Dr. M. Neumann. The Society will meet twice each month.

Removal of Quarantine against Pleuro-pneumonia.—The Secretary of Agriculture has issued a proclamation, under date of September 26th, removing the quarantines heretofore existing in the counties of Kings and Queens, N. Y., and Essex and Hudson, N. J., for the suppression of contagious pleuro-pneumonia among cattle. This completes the dissolving of all quarantines established by the Department of Agriculture in the United States for the suppression of this disease. It is officially declared that the United States are "free from the disease known as contagious pleuro-pneumonia." The seaboard and frontier inspection will be continued to prevent the reintroduction of the disease into this country.

Dr. Henry Grafton Clark, of Boston, died at Hyde Park, Mass., on September 23d, at the age of seventy-eight years. He began the practice of medicine in Boston in 1834, and retired about two years ago. He was connected with the Massachusetts General Hospital for twenty-five years.

The Value of a Toe.—A workman employed by a dredging company in New Jersey had three of his toes cut off by one of the machines, and sued the company to recover $10,000 damages. The jury awarded him $1,260, fixing the value of each toe at $420.

Dr. José Miguel Perraza died recently in this city, at the age of forty-six years. He was born in Santa Maria, Cuba, but having been engaged in a revolutionary expedition was expelled from the island. He studied medicine in Spain and then removed to this city, where he had practised several years before his death.

Antiseptics and Cholera.—Quite a number of experiments have been made regarding the effect of the different germicides upon the life of the microbe. Alcohol, in a ten per cent. solution, stops the development of the comma bacilli only when added in a proportion of one part to ten of the nutritive fluid. As sulphate of iron is frequently used as a disinfectant in an epidemic of cholera, it is important to recognize the fact that it does

not kill the bacilli, but it simply hinders their development. It does, however, stop putrefactive changes which would cause the death of these organisms. The use of this agent, therefore, is to be avoided in cases of cholera. Carbolic acid (one part to four hundred of the nutritive fluid), peppermint oil (one part to two thousand), sulphate of copper (one part to twenty five hundred), quinine (one part to five thousand), corrosive sublimate (one part to one hundred thousand), possess the power of arresting the development of this microbe, and it is possible that they may absolutely cause its death. One very important point was brought out by these experiments, namely, that the comma bacilli die very easily when dried, and this may explain the fact why epidemics of cholera disappear after a certain time. There is a very marked difference between the vitality of the specific germ of cholera and that of small-pox. The former dies a natural death, while the latter may retain its vitality, when dried, for an indefinite period.—Dr. J. H. McCollom, *Boston Medical and Surgical Journal.*

Cancer and Erysipelas.—Attacks of erysipelas are said to have a favorable effect on the course of certain forms of insanity, particularly lypemania. Erysipelas inoculations have had also an appreciably good effect upon sarcomatous growths. It is stated that experiments are now being made to determine whether similar inoculations will not affect carcinoma favorably.

Over Seven Thousand Deaths from Cholera have so far been reported in Hamburg. The epidemic is, however, rapidly abating.

Pan-American Medical Congress.—There will be a meeting of the Committee on Organization of the Congress in Cincinnati at the time of the annual meeting of the Mississippi Valley Medical Association, October 12, 13, and 14, 1892. The preliminary announcement of the Congress will be issued within a few weeks. This announcement will show that the organization has been perfected in almost every colony and country of the Western Hemisphere. The local medical societies in each of the constituent countries are made auxiliary to the Congress, which will be held in Washington, D. C., September 5, 6, 7, and 8, 1893. Dr. Reed, of Cincinnati, Secretary-General of the Congress, and Chairman of the Committee on Organization, announces that the date of the Rome meeting of the International Medical Congress has been definitely set for September 24th of next year. This gives an interval of sixteen days between the Washington and the Rome meetings, during which time an easy trip can be made from the former to the latter city. It is possible that a steamer may be chartered to proceed direct from New York to Rome.

The Cantani Method of Treating Cholera.—Two special measures may be given a thorough trial, hypodermatoclysis and enteroclysis, recommended by Cantani upon the ground that the organism has lost a very large quantity of its water, which must be re-supplied in order to sustain life. For the first he recommends eighty grammes of common salt and six of carbonate of soda, dissolved in two litres of boiling water and cooled. From one to two litres of this fluid is allowed to flow slowly beneath the skin of the flanks through a fountain-syringe and the cannula of an aspirator. The tumor formed by the fluid is slowly rubbed away. He advises the warm bath in conjunction with the infusion. This may be repeated in two or three hours. For enteroclysis, a mixture of laudanum and tannic acid is employed. The formula consists of from five to ten grammes of tannin, thirty to fifty drops of laudanum, and fifty grammes of powdered gum arabic in two litres of boiled water or infusion of chamomile. This should be given early, as soon as it is found that a simple diarrhœa does not yield at once to rest in bed and simple remedies. The rectal syringe is furnished with an elastic tube three metres in length. With this the whole length of the colon can be filled, and often a quantity can be made to pass into the small intestine. The temperature of the mixture and the quantity may vary according to the age of patient.

The Tri-State Medical Association.—The following is a list of the papers to be read at the fourth annual meeting of this Association, which will be held in Chattanooga, October 25, 26, and 27, 1892: "Eye Symptoms in General Disease," by Dr. J. L. Minor, of Memphis, Tenn.; "Talipes Equino-varus" with presentation of patients, by Dr. C. W. Barrier, of Rome, Ga.; "Sequences of Otitis Media Purulenta," by Dr. T. Hilliard Wood, of Nashville, Tenn.; "Report of 1,050 Strabismus Operations, with Some Observations on the Same," by Dr. A. W. Calhoun, of Atlanta, Ga.; "Special vs. General Practice in Medicine," by Dr. W. J. Killen, of Birmingham, Ala.; "Synovitis," by Dr. S. B. Cowan, of Tullahoma, Tenn.; "The Present Status of Medical Education in the South," by Dr. Luther E. Granby, of Atlanta, Ga.; "Pharmaceutical Preparations of the Present Day," by Dr. John C. Le Grand, of Anniston, Ala.; "A Clinical Study of the Relation between Scarlet Fever and Diphtheria," by Dr. W. D. Hoyt, of Rome, Ga.; "The Treatment of Inguinal Hernia," by Dr. J. W. Handly, of Nashville, Tenn.; "Fistula in Ano," by Dr. Andrew Boyd, of Scottsboro, Ala.; "Stricture of the Male Urethra: its Diagnosis and Treatment," by Dr. W. L. Gahagan, of Chattanooga, Tenn.; "Phimosis," by Dr. Erasmus T. Camp, of Gadsden, Ala.; "The Rational Treatment of Enlarged Prostate in Old Persons," by Dr. George W. Broome, of St. Louis, Mo.; "Advanced Theories in Psychical Science," by Dr. John E. Purdon, of Cullman, Ala.; "Drunkenness and Its Gold Cure," by Dr. John P. Stewart, of Attala, Ala.; "Surgery—Things to Do and Things not to Do," by Dr. Willis F. Westmoreland, of Atlanta, Ga.; "A Few Selected Cases in Laparotomy," by Dr. W. H. Wathen, of Louisville, Ky.; "Extra-uterine Pregnancy," by Dr. Richard Douglas, of Nashville, Tenn.; "The After-treatment of Abdominal Operations," by Dr. W. E. B. Davis, of Birmingham, Ala.; "Hepatic Abscess," by Dr. E. B. Ward, of Selma, Ala.; "Report of Treatment of Sterility," by Dr. J. M. Head, of Zebulon, Ga.

Widows.—There are over twenty millions of widows in India, and of these nearly eighty thousand are under nine years of age.

The Next International Medical Congress, it has been decided, will be opened on September 24, 1893, and close October 1st, at Rome.

Krafft-Ebing has been unanimously recommended to succeed Meynert, deceased, in the Chair of Psychiatry in the University of Vienna.

The Mattei Treatment of Cancer was one of the most widely advertised of the numerous medical quackeries which have arisen of late years. It became so widely known in England, and so many testimonials of its wonderful cures were presented, that it received a great deal of free advertising. In response to certain representations made by Lady Paget in a monthly periodical, and by the editor of the *Review of Reviews*, a committee of investigation was formed in the early part of last year, to inquire into the claims of the treatment. The committee consisted of Sir Morell Mackenzie, Mr. Lawson Tait, and Dr. G. W. Potter. It seems remarkable that a nostrum, the composition of which was kept secret, except that it was given out to be bottled electricity of different colors, supplemented by certain globules. should have been the subject of serious investigations; but as several people of influence and education had announced themselves as believers, and as the Matteists openly avowed that they courted full investigation, it appeared that to bring to light its true character would be an important public service. After the committee was ready to work, the champions of the cure began a series of tactics to prevent themselves from being proved impostors. At first, on one pretext or another, they declined to receive for treatment each case of genuine cancer as it was presented to them. After it became evident to the public that they were doing this, they agreed to take five cases of genuine cancer of the breast. These five cases were treated by the Mattei system for a year, under the observation of the committee, but, as was to be expected, they grew steadily worse. The editor of the *Review of Reviews*, who at the outset was a strong partisan of the method, and who appears to have acted in the capacity of an umpire, began to see that the Matteists were not gaining credit by their results. When these five cases were evidently not being cured, the Matteists requested the committee to report on old cases which they produced, claiming that they had already been entirely cured. This the committee declined to do, and the champions of the treatment began to make technical objections to different points of the investigation. Finally the investigation ceased. The "electricities" so called were found to be composed of distilled water.—*British Medical and Surgical Journal.*

Reviews and Notices of Books.

Uric Acid, as a Factor in the Causation of Disease. By Alexander Haig, M.A., M.D. Oxon., F.R.C.P. London: J. & A. Churchill. 1892.

This book comprises one of the most thorough investigations to date. The author writes very clearly, so that anyone can comprehend the significance of uric acid. The careful experimentation is worthy of note, and the action of the drugs on the human economy is such that each effect is considered. The chapters on the action of the salicylates, quinine, morphine, headache, epilepsy, rheumatism, gout, diabetes, Bright's disease, deserve especial mention.

Text book of the Eruptive and Continued Fevers. By John William Moore, B.A., M.D., M.Ch. Dublin. William Wood & Co., New York. 1892.

Dr. Moore has carefully compiled in this text-book a complete résumé of the eruptive fevers. It is eminently practical for the busy practitioner of medicine, and goes into very elaborate details, giving all modern views and researches to date. A valuable addition, and of great service, will be found the charts of temperature in all the different fevers. The bacteriological examinations are well worthy of note. The most welcome portion of this work will be the treatment of the various febrile diseases and the prescriptions contained therein. It is safe to say that this book will be an ornament in the library and of valuable assistance in practice.

De la Périnéotomie et de ses Applications. Par le Dr. Charles Uillems, Assistant à l'Université de Gand. Avec 4 Planches en Phototype. Gand: H. Engelcke; and Paris: Vve Babé et Cie. 1892.

In this work the author makes a very strong plea in favor of perineotomy in many cases where now laparotomy is employed. Among the applications of the operation which he advocates, are its ease of performance and its practicability. He commends it for many cases of extirpation of the rectum, diseases of the prostate and bladder, recto-urinary and recto-vaginal fistulæ, extirpation of the uterus, and in the removal of intra-pelvic tumors. All the details of the different operations described were carefully worked out on the cadaver, but the author has not yet proved the practical value of the operation in all its applications upon the living subject. There are four plates, made from photographs, which assist in the elucidation of the subject.

Transactions of the American Pediatric Society. Third Session, held in Washington, D. C, September 22 to 25, 1891. Edited by William Perry Watson, A.M., M.D., Recorder. Volume III. Printed by Fairchild & Co. 1892.

This is a complete report of the transactions of the Pediatric Society, giving the papers read at the meeting with the complete discussion, and embodying all that transpired at the Washington meeting, held September 22 to 25, 1891.

Elements of Materia Medica and Therapeutics, Including the Whole of the Remedies of the British Pharmacopœia of 1885, and its Appendix of 1890. By C. E. Armand Semple, B.A., M.B. Cantab., M.R.C.P. Lond., Secretary to the Court of Examiners, and to the Board of Examiners in Arts of the Apothecaries' Society; late Member of the Court of Examiners and Senior Examiner in Arts of that Society; Physician to the Bloomsbury Dispensary. With 440 Illustrations. London and New York: Longmans, Green, & Co. 1892.

The book is concise and complete, giving the method of preparation, characters and tests, official preparations, therapeutics, and dosage of every drug in the British Pharmacopœia. The illustrations are very numerous, showing plants, crystals of minerals, methods of preparation, and numerous other things connected with pharmacy and materia medica. The book will prove of great value to students as a book of reference, and to all physicians who may be weak in their pharmacy and therapeutical knowledge.

Caffeine Stimulants.—In England the consumption of tea is rapidly increasing and coffee diminishing. Cocoa has increased thirty-four per cent. in five years.

The Incubation Period of Cholera varies from one to fifteen days, and averages two to five days.

A Serious Blunder.—Two dozen bottles of henbane-seed, labelled celery-seed, were recently sold in England. Some cases of poisoning resulted, but none terminated fatally. All but two of the bottles have been recovered.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Seventeenth Annual Meeting, held at Brooklyn, N. Y., September 20, 21, and 22, 1892.

JOHN BYRNE, M.D., OF BROOKLYN, PRESIDENT.

FIRST DAY, TUESDAY, SEPTEMBER 20TH.

Address of Welcome.—DR. CHARLES JEWETT, of Brooklyn, gave a brief address of welcome to the members on this the Society's first visit to their city of nearly a million inhabitants. A cordial welcome was extended by the resident Fellows, by the Brooklyn Gynecological Society, by the Medical Society of the County of Kings, and by the General Profession of the city. They hoped to fully reciprocate the hospitalities which had so often been extended the local Fellows at the meetings in other cities.

Periodical Inter-menstrual Pain.—DR. CHAUNCEY D. PALMER, of Cincinnati, read the first paper, which was on a subject treated of by him in an article published in the *American Journal of Obstetrics* last March. He had seen and had under his care for months at a time, within the last twelve years, five to six cases, distinctly pronounced, of what he would call periodical inter-menstrual pain. The symptomatology was, at a certain time following menstruation, generally about the middle of the inter-menstrual period, there had been attacks of pelvic pain, located in either ovarian region, sometimes on one, again on the opposite side. These pains varied in severity and duration, were usually short, usually intermittent, came on at night as well as during the day, continued two to nine days, were uninfluenced by bodily movement, were unattended by febrile phenomena. The literature of the subject was limited, but it had been written upon briefly by Coe, Oldham, Olshausen, Tait, Thomas and Mundé, Pozzi, etc. The conclusions arrived at by the author were: 1, Periodical inter-menstrual pain is a comparatively rare disease; 2, the disease is ovarian, not uterine; 3, it is an oöphoritis, or peri-oöphoritis, or both; 4, the chief underlying exciting cause of these attacks of pain is the morbid obstruction to the extrusion of the contents of the Graafian follicles; 5, many other morbid conditions (uterine, peri-uterine, or ovarian) may be associated with the oöphoritis, but their presence is not the cause of the essential symptoms; 6, cure is effected only by overcoming the disease of the ovary or by its extirpation.

Complications During and After the Operation in a Few Recent Cases of Abdominal and Pelvic Surgery.—DR. W. H. WATHEN, of Louisville, opened this paper by cautioning the young men in the profession against allowing their enthusiasm to lead them into doing operations which might or might not redound to their glory while proving of no benefit, or disastrously, to the patients and bringing discredit upon scientific surgery.

The cases reported from his practice of the past year, it was hoped, might teach us to do better work by learning how to treat complications and prevent accidents.

The first case was that of a woman, referred to him by a surgeon in Missouri, with a diagnosis of pelvic abscess on the left side. In July, 1891, the patient had begun to suffer severely in the left inguinal region, temperature and pulse increased. Tumor felt in the left side of the pelvis extending into the abdomen. After several weeks the pain and fever subsided and the patient thought she was well, until, in July, 1892, she had a recurrence of pain and fever, and again noticed the tumor. Correct diagnosis impossible, but the necessity for laparotomy was positive. Dr. Wathen opened the abdomen August 20th, found the omentum thick, signs of extensive chronic peritonitis, firm adhesions, tumor found to be an imbedded broad-ligament cyst, which had not only unfolded the layers of the broad ligament, but had stripped the peritoneum from the posterior pelvic wall to a point above the sigmoid flexure of the colon, separating the layers of the meso-colon so that the mesenteric surface of the bowel was attached to the thin cyst-wall. The bowel could be traced on the anterior surface of the tumor over to the right side. Uterus enlarged to three times its normal size, peritoneal covering partly separated, exposing muscular coat. The patient made an uninterrupted recovery.

The second case was that of a woman who had had pain and pressure in the region of the uterus six months. Dr. Wathen felt exudates on both sides of the organ larger than an orange. Exploratory laparotomy was performed, a band of omentum nearly as wide and thick as the hand was found attached to the right broad ligament in the region of the severe pain. It was ligated in two places and divided. The enlarged uterus and the exudates in the broad ligament were united in one solid malignant mass. The uterine mass had insinuated itself under the sigmoid flexure. The patient had since had no pain nor fever, but the ultimate result naturally would be fatal.

The third case proved to be one of extensive adhesions from peritonitis which probably had been caused some time before by a fall.

The fourth case proved to be one of extra-peritoneal abscess of appendicial origin in the right inguinal region, although the appendix could not be found. The patient recovered.

In the fifth case, in which he extirpated the uterus for malignant disease, the nurse, for some unknown reason, during convalescence, gave a vaginal injection of bichloride, 1 to 2,000, which penetrated into the peritoneal cavity. Nevertheless, the patient recovered.

Case of Lithopædion.—DR. WILLIAM T. LUSK, of New York, presented a lithopædion, or calcified fœtus, which had remained in the mother's abdomen thirteen years. It was not until after certain symptoms had arisen to indicate laparotomy and the mass had been removed that the mother recalled the fact that, thirteen years before, she had been in labor pains which ceased, and she and her physician afterward were subjects of mirth among her friends. Only a short time afterward Dr. Lusk met with another case which appeared to be similar, the similarity persisting during the operation, but instead of a lithopædion the mass was a calcified fibroid.

DR. MANN, of Buffalo, related two cases in which he had operated and found a lithopædion, the pregnancy having taken place some years before.

The Elective Cæsarean Section; the Most Favorable Time for Operation.—DR. HENRY C. COE, of New York, read the paper. One's experience with this, however limited, should be recorded, especially in America, where few operators had had a personal experience with more than four cases. The United States had, however, contributed a fair proportion of the successful cases of the Sänger operation of the last decade, seventy in all, with a maternal mortality of forty per cent. With a tinge of local pride Brooklyn and New York Fellows of this Society could point to eighteen cases, performed by nine different surgeons, with a mortality of thirty-three and one-third per cent., four of the six fatal cases having been particularly unfavorable, while one death, the case of Dr. Grandin's, was due to puerperal mania and could not be referred to the operation. It was interesting to note that the ten cases reported since 1889 had been practically elective and that they were all successful.

The question was asked, Should we choose our own time for operating or allow this to be determined for us by the onset of labor? It was curious to note the uniformity with which writers on obstetrics repeated the injunction, Do not operate until labor has begun! The dangers which it had been urged would be incurred by disregarding this rule were serious hemorrhage, due to imperfect contraction of the uterus, and retention of the lochial discharges by reason of non-dilatation of the cervix. But the author was convinced that these dangers were purely imaginary, and based solely on theory. His

own experience, although limited to two cases, entirely accorded with the position taken by Harris, that, other things being equal, we increased rather than diminished our chances of success by operating before the commencement of labor. The advantages to be secured by operating before labor could be summarized as follows: To the surgeon—(1) after obtaining all the needed counsel, he set his own time for the operation during the day, and was not summoned hurriedly at night to operate by imperfect light and without his regular corps of assistants; (2) he secured the same conditions as in ordinary cœliotomy—thorough preparation of the patient, rooms, instruments, etc; (3) since the patient was in the best possible condition, he was not hurried, was not obliged to "work against time," slurring those numerous minor details which were so essential to success (this was all-important to American surgeons, the majority of whom were necessarily tyros.) To the patient—(1) she was spared the suspense incident upon long waiting (we recognize the importance of the *morale* in ordinary cases of abdominal section, how much more important here, where two lives were at stake!); (2) having been thoroughly prepared for the operation, she went to the table in such a condition that the element of shock was reduced to a minimum, and the subsequent convalescence was more rapid and uncomplicated; (3) asepsis was perfect. As no examination of the genital tract had been made on the day of the operation, there was no chance for infection in this way. Sepsis could never be positively excluded under contrary conditions, especially where labor was induced in the usual manner.

The author had sought to show as concisely as possible that the two essentials to success—early operation and perfect technique—were intimately related to each other, so that in securing the one we secured the other. The elective operation should be made such in every sense of the word; it should be subject to the same rules as those which governed ovariotomy or abdominal hysterectomy. The time to be chosen was near the end of pregnancy, but before labor had begun. Hemorrhage need not be feared, the danger of shock was lessened, and sepsis was eliminated. The author then gave the histories of two successful cases operated upon by himself by elective Cæsarean section.

The Remarkable Results of Antiseptic Symphysiotomy.—Dr. Robert P. Harris, of Philadelphia, sent a contribution on this subject which was read by the Secretary, Dr. Coe. It reviewed the subject in the author's usual analytical, painstaking, and conscientious manner.

It would be profitable, he said, in marking progress, to look back to the early days of symphysiotomy, and note what occurred under the first forty operations, dating from 1777 to 1804. Women recovered, 25; died, 15; children saved, 12; dead, 28. The results of the second forty were about the same. From 1777 to 1858 there had been fully one hundred operations, and more than this since 1865.

To Professor Morisani must be given the credit of reviving the operation, and of having continued to persevere with it until its technique had become perfected and its rate of mortality reduced to the lowest possible figure. He commenced to study symphysiotomy on the cadaver in 1863, and first operated upon a living woman in 1866, saving both mother and child. But in other hands, with less care, the operation was less successful, for in Morisani's report in 1886 there had been in 18 operations loss of 8 women and of 5 children. Continuing, but using greater care, 13 different operators had, since 1886, delivered 40 women by symphysiotomy, 6 of the women enduring two operations with success, and 35 of the 40 children were saved.

Here we had an operation which had been characterized by Baudelocque as murderous and unphilosophical, converted, by subcutaneous section and rigid antisepsis, into a safe surgical measure, without even the dreadful lameness which was once urged against it, the symphysis being readily made to reunite firmly under proper fixation of the pelvis. It was true that in four instances there was produced a fistula of the bladder or urethra, which Morisani claimed should not occur under proper precautions.

Two inches and a half of separation, on the average, were all that should be claimed as safe in the living woman. The operation was not practicable on a Robert or Naegele pelvis, or in one where there was coxalgic anchylosis; nor in cancer of the cervix; nor in cases where the cervix would not dilate; nor in obstructions from exostosis, tumors, etc. A minimum pelvic contraction to $2\frac{3}{4}$ inches was safer than Morisani's minimum of $2\frac{3}{8}$ inches.

The author considered the question of choice between the three incisive methods of delivery in cases of contracted pelvis: the improved Cæsarean, the Porro Cæsarean, and symphysiotomy, and gave the technique of the latter. Obstetric surgeons were likely to prefer the improved Cæsarean section, especially as it was possible, under most favorable circumstances, to reduce the maternal mortality to six per cent. The author's table represented all the 40 women operated upon by symphysiotomy since 1886 as having recovered, except one; while 35 of the children lived.

Cœliotomy after Labor.—Dr. William H. Parish of Philadelphia, read this paper. He said that in dealing with abscess in the pelvic connective tissue, or within the tube or ovary, or when encysted within the peritoneal cavity, all obstetric surgeons probably recognized the imperative rule that the pus must be evacuated, usually with the knife and early in the progress of the case. The fact that exceptionally cure might take place from spontaneous rupture did not in the mind of the surgeon make interference less necessary. Although the necessity for surgical interference was thus universally appreciated by operators, yet it too often happened that the physician did not extend practical recognition to the necessity for early diagnosis of suppuration, and for early resort to surgical relief. Too often the operator was called when prostration from blood infection, etc., made recovery extremely improbable. There was still a wide-spread belief that when suppuration took place after child-birth it was usually located in the pelvic connective tissue, and that it was best to wait for fluctuation or bulging in the vagina before attempting evacuation. As a matter of fact, the pelvic connective tissue was not the usual site of the suppuration. When here situated the pus was usually evacuated per vaginam or above Poupart's ligament external to the peritoneum. But in some cases a median cœliotomy might be indicated as an aid toward ascertaining the location of the pus when its location was not known. The operator who expected never to meet with suppuration in the pelvic connective tissue might at times open unnecessarily the peritoneal cavity, when the much simpler and safer procedure of extra-peritoneal incision, either in the vagina or above Poupart's ligament would suffice.

It was well known ovarian cystomata, dermoids, hydro-, hæmato-, and pyo-salpinx did not render pregnancy impossible, and labor, by reason of torsion, contusion, or rupture, established localized or general peritonitis; and if the symptoms did not promptly subside there existed an absolute indication for cœliotomy, with removal of the offending mass and with irrigation. But exceptionally, the peritonitis and other evidences of infection might be merely transitory and operation be safely deferred.

For a long time it had been recognized that abscess might occur in the uterine parenchyma after labor, and it had been recommended that in such a case the uterus and its appendages be removed. Doubtless, when the abscess was of large size, or the septic infection of the uterus was far advanced, the operation was the only one justifiable; but the author had had one case which

lowed that total extirpation was not always necessary. His patient recovered after evacuating the mural abscess, and taking out a V-shaped piece.

The encysted pus sometimes accompanying puerperal peritonitis, local or general, was at times very great, as in one case in which he operated three gallons were drawn off, yet the patient made an excellent recovery. Such cases have sometimes been mistaken for diffuse suppurative peritonitis. Plastic peritonitis existed in all such cases, and was conservative after the formation of pus. Diffuse suppurative peritonitis rapidly terminated fatally, and the pus was diffused over the peritoneum, although most abundant in the pelvic region.

During the progress of plastic peritonitis cœliotomy was rarely indicated, unless pus was present. Yet not infrequently this form of peritonitis was dependent upon an abscess within a tube or ovary, etc.

In diffuse septic suppurative peritonitis the rapid tendency to death rendered cœliotomy quite hopeless and unjustifiable, if deferred until the peritonitis was well advanced. The experience of surgeons, at most, had not been reassuring, for he knew of no case of operation ending in cure, and he asked whether the invariably fatal result had been due to lateness of the operation. Removal of the uterus and its appendages, with irrigation, though rational as getting rid of a large supply of infectious material, yet would increase the shock, and add much to the danger of simply opening the abdomen and irrigating. Perhaps it would be wiser to limit one's self to abdominal irrigation, supplemented by uterine curetting and douching.

The author had performed cœliotomy eight times after labor, with one death. In every case there was pus and limited peritonitis.

Usually the dull curette with repeated douching would suffice the first few weeks of the puerperium, and he had his fears of the safety of the cutting instrument in the uterus during this period.

Certain Aspects of Gonorrhœa in Women.—Dr. Charles P. Noble, of Philadelphia, read this paper. Prior to 1873, when Noeggerath published his celebrated paper, our knowledge of the natural history of the disease was very incomplete, and no adequate conception of the relation of gonorrhœa to endometritis, salpingitis, and peritonitis existed. Noeggerath's apparently exaggerated conclusions forced the subject upon the attention of the profession, and knowledge of it had steadily grown since. An interesting and serious phase of gonorrhœa in women, was the invasion of the womb, tubes, ovaries, and peritonium. This extension of the disease was known to Bernutz, forty years ago, but its real frequency was not appreciated until demonstrated by the daily work of the modern abdominal surgeon. In illustration of this form, the author related a case in a woman, free from genital catarrh, who contracted gonorrhœa of the cervix and vulvo-vaginal gland, with little if any involvement of the vagina; yet it spread promptly to the tubes and caused a large collection of pus within the peritoneum. The pus was not examined bacteriologically. How the disease spread to the tubes, ovaries, and peritoneum was still in dispute.

The more recent studies of Wertheim had led him to conclusions which agreed with clinical experience. He was able to demonstrate that the gonococcus would produce peritonitis in white mice. As the mucous membranes of white mice were refractory to gonorrhœa, while those of man were susceptible, he argued that this fact went far to show that the gonococcus could produce peritonitis in man. He had demonstrated also that the gonococcus could penetrate pavement as well as cylindrical epithelium. He claimed that the gonococcus could penetrate the connective tissue and infect lymphatics. He had demonstrated gonococci in pus from an ovarian abscess. If Wertheim's observations should be confirmed, gonorrhœal ovaritis and abscess, peritonitis, and rheumatism would receive a satisfactory bacteriological explanation.

The author spoke of the chronicity of gonorrhœa, which had also been first emphasized by Noeggerath. He also discussed the question whether gonorrhœal salpingitis ever resulted in a perfect natural cure with a functionally active tube. He had never seen a case with such a result. Speaking of the likelihood of the second tube and ovary becoming infected if one were removed for disease, the author would advise extirpation of the sound one also in elderly women, and let younger women decide for themselves whether they would take the risk of a second operation.

All who discussed this paper doubted whether double gonorrhœal salpingitis was ever cured in the sense of permitting subsequent pregnancy. The chronicity of the disease was dwelt upon.

Retro-peritoneal Tuberculosis Simulating Hernia.—Dr. Edward P. Davis, of Philadelphia, read the history of a case of this nature. It occurred in a woman who began to suffer from pain in the right inguinal region following the lifting of a heavy weight. She was kept in bed eleven weeks, during four of which she had metrorrhagia. On recovering she resumed her work as a domestic, but some time afterward was again seized with severe pain in the right ovarian region. When she was seen by Dr. Davis she was well nourished, thoracic viscera normal, abdomen moderately distended; a swelling in the right inguinal region which resembled a hernia; temperature from 100° to 102½° F., pulse rather rapid. She gave a good history; her father, however, had died of tuberculosis. It was believed that she had a hernia or tubal disease. The tumor was cut down upon and the resemblance to a hernia persisted during the dissection of the sac. It was utterly impossible, however, to reduce the tumor, and as the patient was about to pass into collapse, the abdomen was hastily opened in the median line, and while the finger was trying to return the mass it penetrated an abscess, which contained several ounces of pus. The pelvic peritoneum was thickened and engorged, and in the hypogastric region was commencing peritonitis. Briefly, it became evident that the disease had had its origin behind the peritoneum, and must have been of the nature of tuberculosis. As was usually the case, the pus in the tumor did not contain the tubercle bacillus. The patient made a good recovery, and had shown no signs of tubercular or other disease since.

Accouchement Forcé in Certain Obstetrical Complications, with Remarks on the Treatment of Post-partum Hemorrhage.—Dr. Egbert H. Grandin, of New York, read this paper. Obstetrics of to-day, he said, were very different from formerly. Methods which in the past had been condemned were now recognized as appropriate, especially because of the introduction of antiseptic surgery. Chief among the valuable methods which had been rendered safe by antiseptic principles, were accouchement forcé and tamponade of the uterus. In recognition of these truths, he wished to submit to the criticism of the members certain arguments in favor of accouchement forcé in some obstetric complications, and to lay before them what he considered the treatment *par excellence* of post-partum hemorrhage. Several cases were related by way of illustration, one of which was the following: A multipara, eight months gravid, had hemorrhage, her doctor inserted a vaginal tampon. When Dr. Grandin was called her pulse was rapid and thready, the facies that of the loss of blood, the condition indicated necessity for rapid evacuation of the uterus, primarily in the interests of the fœtus, secondarily those of the mother. He withdrew the gauze from the vagina, inserted the whole hand, found the cervix one-eighth dilated, the margin of the membranes presenting. He separated the margin of the placenta, introduced the finger, thirty minutes being required for dilatation; then bi-polar version was performed, the fœtus extracted, the placenta removed, and the patient thus spared all further loss of blood. The uterus was packed with gauze. Satisfactory recovery.

Several other cases which were cited, in which the same procedure was resorted to, were types of uræmia, threatened or actual, and of disproportion between the size of the pelvis and the fœtal head, etc.

In all of these cases the results were quite satisfactory, and he asked the members to compare them with such as not infrequently followed temporizing and slower methods. He had acted in the interests of the child as well as those of the mother. One of not the least advantages which modern obstetrics possessed over the practice of the past was that the interests of the mother stood not necessarily in opposition to those of the child.

The author impressed the greater safety of bringing on labor with the sensitive hand, over manipulations with instruments in the dark.

What were the objections to the method? In the first place, it might be claimed that uterine atony might result, with the serious effect of post-partum hemorrhage. This, however, did not hold good at all in placenta prævia, while in threatened uræmia venesection was a good thing. When the method began to be advocated for post-partum hemorrhage, he had objected to it because of its possibly preventing contraction, but practice had shown that this objection was purely theoretical, for gauze introduced into the uterus really favored contractility of the uterus, and the organ speedily regained its tone. He now favored its use wherever hot injections failed to cause a response. The second objection to accouchement forcé was that it might injure the cervix. While this had not occurred to him he did not doubt that it might, but its possibility would not deter him from resorting to a method for obtaining a living child. Besides, other methods involved about equal risks in this direction.

The President's Address.—Dr. John T. Byrne, of Brooklyn, President of the Society, read a lengthy address, which was devoted chiefly to contrasting the two operations for uterine cancer—electro-cautery and vaginal hysterectomy. First, he thanked the Society for the honor conferred upon him when it had elected him to fill the high position which had been so ably filled by such distinguished predecessors as Dr. Fordyce Barker, etc. He alluded also to the reference in the President's address of last year to the too great frequency with which women had been mutilated sexually, and said this abuse was rapidly being corrected. It was desirable, however, to again call attention to as great an abuse, that of unnecessary speculum examination of young unmarried women.

The President thought that three papers were sufficient to read at each session of the Society, or eighteen in all, if enough time would be given for discussion. He then passed to a review of the statistics on which it had been attempted to justify vaginal hysterectomy for cancer of the uterus, and stated his reasons for urging the adoption, instead, of the safe operation of partial amputation by the electro cautery.

He had often been asked to explain what at first thought appeared to be a transparent incongruity, namely, why better results should follow or be claimed for amputation of a cancerous cervix by galvano-cautery than for the same operation by other means, or, above all, the extirpation of the entire uterus. At first he could do little more than point to clinical facts and venture to surmise that coincident with either of the latter surgical procedures there might take place a traumatic infection in parametric tissues, which, though apparently healthy, were, in all probability, already predisposed in some special manner to pathological changes. Increased experience in the treatment of uterine cancer by the galvano-cautery had rendered it more than probable that this was the correct explanation. Proliferation in outlying tissues seemed to be hastened by the knife, while the cautery had an opposite effect.

Further comment on the statistics given, even did time permit, would, he thought, seem uncalled for. They spoke for themselves, and in his opinion so emphatically that "they who run may read." From the the following conclusions, essentially those arrived at Dr. Jackson five years ago, could be drawn:

1. The ambiguous manner in which the statistic tables of vaginal hysterectomy have been constructed so misleading, and in some instances so suggestive of e roneous inferences, as to render the compilers open the charge of *suppressio veri* or *suggestio falsi*.

2. Any operation known to be attended or follow by an average primary mortality of over fourteen p cent. in the hands of the most experienced surgeons is grave and a dangerous one, and demands for its justific tion a large percentage of *permanent* cures.

3. The frequency and rapidity with which recurren takes place after vaginal hysterectomy for cancer, ev when the disease has appeared to be limited and circu scribed, prove conclusively that it can lay no just clai to this essential feature.

4. As the average period of life in cancer of the uteru when not operated upon, is not less than two years, b often more, suffering has not been lessened but aggr vated, and life has not been prolonged, but shortened the vast majority of all cases thus far subjected to vagin hysterectomy.

5. As in twenty-eight cases of vaginal hysterectomy f cancer of the fundus at the Berlin Clinic no fewer tha seven died from recurrence within twelve months, th grounds on which some have conceded to this operatio even a limited field, are inconsistent with facts, and there fore not tenable.

6. As the operation is, in many respects, more dange ous than the disease for which it is undertaken, and, a the majority of all patients afflicted with uterine cance would live longer without than with it, it is not a safe c a useful operation and as such is unjustifiable.

7. On several occasions during the past twenty years and more particularly in a paper read before this Societ three years ago, ample and convincing proof, clinical an statistical, was presented as to the claims and uniqu characteristics of the electro-cautery in the treatment c uterine cancer, and further observation has been mor than confirmatory of opinions then advanced.

8. Amputation of a cancerous cervix by the cauter knife is free from danger, a safeguard against all infection traumatic or septic, and, what is of still greater impor tance, it is destructive to latent cancer-cell proliferatio in tissues far beyond the line of incision, hence muc more is comprised in the operation than the mere re moval of a part or parts not more actively involved i the work of destruction.

9. Any method of operating for which advantages s vital and so far-reaching can be claimed and established and which thus distinguish it from all others, renders its adoption on the part of those who undertake to operate for cancer of the uterus no less than a moral obligation.

Vaginal Hysterectomy for Cancer of the Uterus.—Dr. H. J. Boldt, of New York, in a paper on this subject, devoted special attention to certain points in the operation, and to certain reasons why he preferred total extirpation to any form of partial removal. Regarding the method of operating, he expressed a preference for ligatures when it was possible to use them, but said that in certain cases he had found it convenient, if not absolutely necessary, to use clamps, and so far as his own statistics went, it would appear that the one method was as safe as the other. As to the form of suture, he had persistently used catgut for several years, and, with Dr. A. P. Dudley, had been the only consistent advocate of this material. He considered silk ligature in this operation a nuisance. It prolonged convalescence and could not be rendered more nearly antiseptic than catgut, while with care the latter could be tied quite securely. He impressed the necessity for keeping well outside the diseased tissue. One or two years ago he held the view, which was yet entertained by some, that it was advisable to operate even though one could not remove all infiltrated

sue, but further experience had led him to abandon this actice. The patients did not live so long as if the eration had not been performed, their suffering was ater, there remained some discharge and some hemorrge, which might be profuse. In short, the patients were rse than if total extirpation had not been done. It uld not be forgotten, however, that an apparent malig- nt infiltration causing immobility of the uterus might in lity be due to a previous simple inflammatory exudate that event he would not hesitate to remove the entire rus, although it might be immobile. In this country, n in large cities, not more than fifteen per cent. of all ses of cancer of the uterus that reached the surgeon re suitable for total extirpation of the uterus. It was be hoped that general practitioners would learn to rec- nize the disease earlier.

Regarding operations by partial ablation in cancer of uterus, he quoted a number of cases in current litera- e in which it was found that a nidus of disease in the vix, the only apparent pathological condition before irpation, was separated from disease in the body of the gan by an isthmus of healthy tissue. Because of the im- ssibility of saying before one had the entire uterus in his nd that the body of the organ was not involved as well the porta, he thought he would do hysterectomy in all ses where the extent of the disease did not contra-indi- e it. It was true, the president had advanced some ighty arguments in favor of the electro-cautery, but e author was not yet convinced.

Supra-vaginal Hysterectomy, with Sub-peritoneal eatment of the Stump without Ligature, in Operations Uterine Fibro-myomata.—Dr. B. F. Baer, of Phila- lphia, said it was his object in bringing this paper be- e the Society to call attention to a new management of e cervix in supra-vaginal hysterectomy. If the method uld prove as successful in the hands of others as it had his own it would grow in favor, for he had had nine con- utive cases, all of which recovered. Since writing this, wever, he had had a tenth case, which resulted fatally; t for this result, as he went on to show, the method of erating could not at all be held responsible. A part of e paper was devoted to the consideration of the reasons ich had led different operators to abandon abdominal ation of the stump and for resorting to various modes procedure.

Dr. Baer's operation resembled more nearly that of r. Goffe and Dr. Dudley than any other; yet he said ere was the greatest difference between them, and he ped the two would not be mixed in the minds of his arers.

He operated preferably with the patient in the Trende- nburg posture. The first step after opening the abdomen as to throw a silk ligature around the broad ligament on e side, after which the tumor, etc., were to an extent parated from the uterus. The same step was taken on e opposite side. The knife was then run lightly around e uterus an inch or two above the peritoneal reflection the bladder in front and a little lower behind; the ritoneum was stripped down by the handle of the alpel to make flaps. The next step was to ligate the erine arteries close to the cervix. The organ was then nputated at the cervix, leaving none of the supra-vaginal rtion. When the cervix was dropped it receded deeply to the pelvis and was covered over by the peritoneal ps, which usually were not sutured together. Not a ngle ligature or suture was put into the cervix, which as an important feature in Dr. Baer's operation, as ereby all occasion for sloughing, which had sometimes llowed from a constricting ligature or suture in the other eration, was avoided. In his cases there had been no emorrhage, no sloughing, practically no rise in tempera- re, and no untoward result whatever. He did not uterize the cervical canal. Death in his tenth case took ace in thirty-six hours after the operation and was due the action of the anæsthetic, aggravated by a large itre.

Supra-vaginal Hysterectomy for Uterine Fibroids; Report of Seventeen Cases.—Dr. William M. Polk read the paper. The seventeen cases represented different methods of dealing with the stump, and while the result was not against any one of those tried, yet that described below had finally been adopted. Two of the patients had died. He had also performed supra-vaginal hysterectomy for procidentia in four cases, making in all twenty-one.

The usual incision was made in the linea alba, extending it well down to the symphysis. The ovarian vessels were then tied in position, the first ligation being made, if practicable, outside the ovary. A ligature or forceps was then applied about the same vessel well up against the uterus to provide against the return flow. The upper part of the broad ligament and round ligament were next tied, next the ovarian vessels were divided between the ligatures, and the uterus was cut free from the round ligament and broad ligament well down to the base and lifted from its bed. If the tumor was large and unwieldy, a rubber ligature was thrown around as low down as possible and the structure above cut away. If it were of reasonable dimensions, he proceeded at once to ligate the uterine vessel on each side, then cut the uterus away from the vagina. Now introduce four long catgut sutures, passing one through the anterior vaginal wall, thence to the edge of the peritoneum reflected from the bladder; another through the posterior wall and the cut edge of the peritoneum dissected from the back surface; one upon each side, placed so as just to bring the peritoneum together at the sides of the stump of the vagina, passing thence through the lateral vaginal wall. These sutures were each tied in position and then tied together in a knot which was thrust into the vagina, seized with a forceps and drawn well downward, thus turning in the peritoneal surfaces. The vagina was then washed out and packed with gauze, the packing resting against the inverted peritoneum in the majority of cases, but in some where there had been much handling of tissues, it might be extended between the folds. In this latter class of cases a glass drainage-tube was introduced to the bottom of Douglas's cul-de sac from above. The abdomen was then closed. The drainage-tube was removed in twelve to twenty-four hours, the gauze on the third day.

In procidentia he did not drop the stump, but attached it to the abdominal walls to avoid the possibility of prolapse.

Can We Prevent Secondary Hemorrhage After Ovariotomy?—Dr. H. T. Hanks, of New York, discussed this subject in a brief paper. That it was worthy of consideration was evident from the fact that even today good surgeons occasionally had hemorrhage after ovariotomy. He had himself had two cases; in one the patient died, and in the other he was able to save her life by reopening the abdomen and securing the point of hemorrhage. It was necessary also to resort to transfusion. Three years earlier he had seen two cases in the practice of a friend, in one of which he himself reopened the abdomen, transfixed the pedicle, employed a saline solution, and saved the patient's life. He had known of no fewer than ten deaths from this accident within the last five years. Could, then, rules be formulated for its prevention? This question was especially worthy of consideration by the younger members, who might have judged from their work that there was but one way of fastening the pedicle. The same procedure should not be practised where the pedicle was wide and flat as where small and round.

Where the tumor was large, after ligating the large artery and tying it as tightly as possible, quilt the broad pedicle in and out so that under no circumstances could the silk slip. In smaller pedicles, discover the artery if possible before transfixing, and pass a transfixing needle to one side of it and tie thoroughly. In other words, in small pedicles, be sure not to split the artery or tear the pedicle by too much traction in tightening the ligature.

In removal of the diseased tubes and ovaries, if diseased, and embedded in old adhesions, there would be only small arteries to deal with, and almost any well-tied ligature would hold. He advocated no special ligature; either silk or catgut would do, but should be quite aseptic. If catgut were employed, make the first part of the knot with one turn, the second part with two turns.

The Value of the Forceps in Complicated High Arrest of the Breech, with Report of Two Cases—Dr. Edward Reynolds, of Boston, in a paper on this subject justified the conclusions by the recital of two cases of a rather rare condition, namely, arrest of the breech at the superior strait, complicated by dangerous retraction of the uterus.

The first patient had been in labor thirty-one hours, with no progress the last four hours. Immediate interference was thought to be indicated. Under ether the os was manually dilated, the lower segment of the uterus was found closely applied to the child and somewhat thinned. In view of the condition of the uterus it was thought that the passage of the hand above the constricting ring would be extremely difficult and dangerous, therefore the application of the forceps to the breech was adopted. The Vienna forceps were selected, one blade was applied over the sacrum, the other over the posterior surface of the anterior thigh; axis traction-rods were added, and by two or three strong tractions the breech was brought into the pelvis. The forceps were then removed, but it being impossible to deliver the breech by traction with the finger, they were reapplied without rods, when with moderate traction the breech was brought to the vulva and delivered by the finger. Without the forceps, delivery could have been effected only by withdrawing a leg, which would have endangered rupture of the uterus. The child died the fourth day, of convulsions, from hemorrhage at the base of the brain, but there had been no injury to the body internally or externally by the forceps application. The second case was similar; the child lived.

The special point made by the author was that, had the hand been introduced and the leg brought down, rupture of the constricting thin section of the uterus would have taken place; also that, if the forceps had been applied higher on the body of the child, as was commonly taught, some of the viscera would probably have been injured. The fingers should be repeatedly inserted to assure one that the blades of the forceps grasped at the proper place, which in the oblique position was, for one, at the first sacral vertebra, and for the other, upon the femur opposite; and in the transverse position, at the great trochanter.

What is the Best Management of Occipito-posterior Positions of the Vertex?—Dr Chauncey D. Palmer, of Cincinnati, said he had, in this paper, nothing new to offer, but he hoped to offer a rational plan of procedure in occipito-posterior presentations of the vertex. Intelligent treatment of cases of this position implied, of course, a consideration of the mechanism of labor. The author thought only four positions of the vertex need be recognized. A true posterior position was one in which the occiput was not only toward the sacro-iliac synchondrosis, but in which it impinged against the posterior inclined pelvic plane, just as an anterior position was one in which the anterior inclined pelvic plane received the occiput in its downward movements. If the occiput struck the anterior plane its direction would be downward, inward, forward, and outward; if the posterior, its direction would be downward, inward, backward, then outward. Many causes contributed toward directing the occiput on the anterior rather than on the posterior planes, among them being a strongly projecting sacral promontory, the ischial planes, the muscular pelvic floor, the ischiatic ligaments, the psoas-iliac muscles. Much misunderstanding had arisen from a misconception of what constituted an occipito-posterior position. As said, if the occiput played upon the anterior inclined plane, the case should be regarded as of the anterior positic not the posterior, notwithstanding the fact that the c ciput might look not inconsiderably backward. All su cases would naturally undergo, sooner or later, anteri rotation. If the occiput struck the posterior plane, oft it would undergo anterior rotation only on early, we directed efforts on the part of the accoucheur. N ure's forces, which greatly facilitated anterior rotatic were strong uterine action, aided by vigorous volunta propelling power, a good degree of resisting action at t pelvic floor (the site of rotation), and proper flexion of t fœtal head. Posterior rotation was likely to occur wh the occiput struck the posterior inclined plane well bac ward, when the head was of unusual size, when the isch spines were imperfectly developed, and when the pel floor was greatly relaxed. Posterior position meant sl engagement, slow descent, and a possible non-rotation, a posterior rotation. Flexion of the head after dilatati of the cervix was not complete or persistent. No spec difficulty occurred until the pelvic floor was reache Labor was longer, much greater force was require because the distance which the occiput had to travel w greatly increased; the shoulders and the whole of t fœtus became impacted into the pelvis outside of t uterus. While thus more *vis a tergo* was needed, less w afforded.

In diagnosis, the author said palpation of the abc men and auscultation were as important early as w vaginal touch, and should also be utilized during lab It was not always possible to estimate the degree of bac ward inclination of the occiput, or to say whether would undergo anterior or posterior rotation.

The treatment of most cases was simple, and wou depend upon the stage of parturition at which the con tion was recognized. If seen early enough, rotate t child into the anterior position. If not successful, p form podalic version. The latter operation was esp cially indicated if the head were large and hard, or t pelvis contracted. The knee elbow posture favored, w gravitation, rotation of the fœtus as a whole into the a terior position.

In the second stage, the lateral decubitus correspon ing to the direction of the posterior position, he thoug favored rotation. But if the head reached the perine without rotating, aim to promote and increase flexion l, with two fingers during pains, pushing the frontal bo upwardly, generally pressing toward the mother's le Or the whole hand might be used. The forceps mig still be necessary, rotation being left entirely to natu While the application of the forceps, done carelessly or t early, might prevent anterior rotation, causing extensi their use at this time was urgently called for. Betwe their use and the performance of craniotomy, the fute of this patient might rest. The mother exhausted a child dead, craniotomy offered the best chances for t mother. With the child alive most obstetricians wou very properly prefer the forceps. The author had rt endorsed the doctrine that craniotomy was never jus fiable on the living fœtus.

Drs. Grandin and Malcolm McLean believed t sad results of persistent occipito-posterior cases could obviated by recognizing malposition early, and rotati the child, body as well as head; or, possibly failing, ing version before the head engaged.

Umbilical Hernia in the Female, with Report of Five Cases.—Dr. A. Palmer Dudley, of New York, this paper gave a little space to stating some objectio to certain methods of operating for umbilical or vent hernia, particularly that of returning the parts without cising the peritoneum, as practised by Dr. Edebohls, a then related five cases which illustrated the method n adopted by himself, and which he thought possess certain advantages over the other methods. While was a firm advocate of catgut in most operations, here objected to placing reliance upon it for retaining in aptation the divided abdominal walls. Silver wire s

made use of to take the strain, while catgut was employed as a continuous suture for making closer approximation between the surfaces of the wound. The silver-wire sutures were passed through a small rubber cannula, which at the same time did away with the necessity for twisting them, and also served for drainage, and thus obviated the liability to suppuration. In all of his cases he had succeeded in securing union with almost entire absence of suppuration, and with no rise in temperature.

The fourth case was one of enormous ventral hernia, the cellular tissue greatly atrophied, the vermicular action of the intestines was visible through the skin, and it seemed hazardous to operate. An incision was made nine inches long; the omentum was adherent along the entire line of the incision, and a large portion of it had to be removed. After cutting out an elliptical piece of the walls they were drawn together as closely as possible and quilted by continuous catgut suture. They were so much atrophied that it was almost impossible to get sound muscular tissue to cover in the hernia. In addition to the two rows of catgut, seven wire sutures were employed. In spite of the fact that the patient was not expected to live, she made a good recovery without accident, except for slight suppuration about two wire sutures.

His case showed that it was useless to treat umbilical hernia by mechanical appliances. It was his opinion that to open the peritoneal sac was not dangerous, and he would prefer to do this to returning the sac without knowing how many adhesions there were between it and the intestine; this method of treating the scar did away with the necessity of leaving buried sutures; hernia would be less likely to follow laparotomy if operators would be less careless in closing the abdominal incision.

Stomatitis due to Irritation of Epithelial Pearls in the Mouth of New-born Children.—Dr. Henry J. Garrigues, of New York, said that a small epidemic of superficial ulceration of the palate of new-born children, in Maternity Hospital, was the occasion of a careful examination of all the babies, 52 in number; 49 of these had congenital epithelial pearls on the palate. The first 27 children had their mouths washed out immediately after birth, and after each nursing, with the velvety side of a piece of lint soaked in a saturated solution of boracic acid. Of these 12 had a more or less sore mouth, the ulceration always beginning at the epithelial pearls.

In the last 25 cases no washing was done, and not a single one of these got a sore mouth.

The epithelial pearls are small, white, globular tumors of the size of a pin-head to that of a millet-seed, situated in the raphē of the palate, preferably at the juncture of the hard and the soft palate. They are one to five in number. The outer surface is hard, the inner part softer. They are embedded in the mucous membrane. Most of them are covered with a layer of condensed connective tissue. Instead of the round prominence there is sometimes a white line half an inch long in the raphē.

The mass is composed of epithelial cells like those of the mucous membrane of the mouth. The outer layers are the youngest, having polyhedral form and a nucleus, those near the centre are flat and have lost their nucleus.

Similar formations are sometimes found on the free edge of the alveolar process.

Epithelial pearls are not retention cysts, formed by occlusion of glands, but are due to inclusion of parts of the epithelium of the mouth. They are found as early as the eighth week of fœtal life, and disappear in healthy children at the end of the second month after the birth of the child. In badly nourished children they persist longer.

They are found in that particular place because the palate is formed of two lateral projections which gradually unite in the median line, from the front backward.

On the alveolar process their existence is probably due to the growing together of the walls of the dental furrow over the germs of the future teeth.

Diagnosis.—Bednar's aphthæ are similar superficial ulcers, but begin laterally on the place corresponding to the hamular process of the sphenoid bone, and are usually bilateral. Sprue forms white spots, is never congenital, and attacks any part of the mouth irregularly.

Treatment.—The epithelial pearls being physiological, should not be interfered with. If the mouth is washed out at all it should be done with plain water, a soft, smooth rag, and with great care, so as not to wound the epithelium.

If stomatitis sets in by rubbing off the pearls, the best treatment of the ulcer is to swab it with water acidulated with a few drops of acetic acid, and then paint it with borax glycerine (℥ j.–℥ j.). It heals in a week or two.

Officers Elected.—*President*, Dr. Theophilus Parvin, of Philadelphia; *Vice Presidents*, Drs. W. H. Parish and W. H. Baker; *Secretary*, Dr. H. C. Coe; *Treasurer*, Dr. M. D. Mann; *Council*, Drs. B. B. Browne, A. P. Dudley, E. C. Dudley, and Willis Ford; *Honorary Members*, Drs. Robert Battey, of Georgia, and Morisani, of Naples.

Next meeting to be held in Philadelphia, on the third Tuesday in May, 1893.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 24, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	64	19
Scarlet fever	52	7
Cerebro-spinal meningitis	0	1
Measles	24	2
Diphtheria	53	26
Small-pox	10	2
Cholera	2	2
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Hyperidrosis of the Hands and Feet.—A correspondent who has a patient with profuse sweating of the hands and feet, and who has tried various remedies without success, asks for the best means of curing the affection. It is difficult to say which is the best remedy when there are so many that are good, and none that is certain. For sweating of the feet among the soldiers of the German army, applications of a weak solution of chromic are employed. Hebra uses diachylon ointment, and Shoemaker recommends oleate of zinc with starch, salicylic acid, and bismuth, or naphthol and boric acid. Whitla has obtained the best results with powdered boric acid dusted on the feet after a bath, morning and evening, the socks also being impregnated with the same substance. Carbolic acid, lead, alum, tannin, corrosive sublimate, and many other antiseptic and astringent substances have been employed in lotion or ointment, with more or less success. Sulphonal, antipyrine, aromatic sulphuric acid, atropine, dilute phosphoric acid, ergot, and many other internal remedies have been employed for the relief of local sweating, but such methods are not to be recommended in most cases.

Tyndall on Phthisis.—Professor Tyndall is, without question, a scientist of the first rank, but he sometimes uses any but scientific arguments to support theories that are based on other and much more convincing facts. For example, in maintaining the contagiousness of tuberculosis, he asserts that "no investigation has proved that the mortality among physicians by phthisis does not far exceed the average." This may be true enough, but the proper argument to bring forward, if it could be brought, would be that the mortality among physicians by phthisis

does far exceed the average.' We do not believe that statistics would support this argument, although there are many unquestioned facts which appear to prove that the disease is communicable. Professor Tyndall should avoid the attempt to prove theories by hypotheses.

Two Thousand and Seventy-eight Persons die every week in London. During the influenza epidemic this number rose to 3,271.

Heat to the Epigastrium in Heart Failure.—Dr. W. L. Symes reports, in the *Dublin Journal of Medical Science* for September, 1892, a case of heart failure in which there was no pulse, no sound over his heart, no respiration; his eyes were glassy and fixed; he could not swallow; and severe slapping of the epigastrium had no effect. Having exhausted all available stimulants, and recollecting that he had read somewhere of the value of a hot spoon applied to the epigastrium in states of asphyxia or syncope, Dr. Symes took a hot lump of coal from the fire with the tongs, and applying it over the xiphoid cartilage once or twice, was gratified to find it produce powerful contractions of the inspiratory muscles. This was continued for some time, applications being made around the insertion of the diaphragm, until, by degrees, respiration returned, the patient's eyes opened, his heart beat, and the color came back to his face. He then took some brandy, and finally rallied.

Morphine Soirées are said by the London *Standard* to have become a recognized institution in certain Parisian circles.

The Sale of Medical Practices.—The Comitia of the Royal College of Physicians of London recently passed a resolution to the effect, "That this College regards the sale and purchase of practices, or the transfer of patients from one physician to another for a pecuniary consideration, among Fellows or Members of its body, as contrary to the traditions and practice of the College, interfering with the freedom of patients, and derogatory to the position of a physician."

One Hundred and Eighty Thousand Suicides occur every year among the civilized nations of the world; so says Dr. B. W. Richardson.

Railway Surgery.—There are said to be over six thousand railroad surgeons in this country, twelve hundred of whom are members of the Association of Railroad Surgeons. The attempt of the American Medical Association, or of any State Society, to discipline such a large number of men for practising under contract is, of course, certain to fail.

Microbes as Chemists.—In his address at the recent meeting of the British Medical Association, Mr. Herbert McLeod referred to the important part fulfilled by microbes as chemical agents. He pointed out that microbes are capable of producing chemical changes which surpass the results obtained by the chemist in his laboratory. It has long been known, for example, that the transformation of sugar into alcohol and carbonic acid in the ordinary process of fermentation is due to a living organism, and the transformation of ammonia into nitrous and nitric acids in the soil has also been shown to be due to the action of micro-organisms. It is possible to transform ammonia into these acids in the laboratory by oxidation under certain conditions and at a high temperature, but these organisms do the work quite as effectually at ordinary temperatures. The production of toxines by the alteration of some of the constituents of the animal body through the agency of micro-organisms, is another comparatively recent discovery, and one that will doubtless prove to be of the highest possible importance in respect to the prevention and cure of disease.

Rate of Change in the Human Body.—Sir Lyon Playfair says that the entire nitrogenous material in the body is changed in six weeks.

Malarial Fever in Tampico.—Dr. Antonio Matienz has published a memoir containing the results of a stud of malarial fevers occurring in Tampico, Mexico. In al the cases examined by him he found the hematozoon o Laveran in the blood of those suffering from the disease He also found the same organism in the blood of variou birds and of turtles which were apparently in a conditio of health.

Takes His Own Medicine.—"The physician," says ribald contemporary, "is the man who prescribes change and then takes all you have."

Getting her Diploma Under Difficulties.—A lady ha just taken her M.D. degree at St. Louis under circum stances of difficulty to which the inferior male creature fortunately for himself, can never be exposed. A fe weeks before the date of examination she presented he husband with a ninth "olive branch," and eleven day after the interesting event she was again in her place i the lecture-room.

A Death Sentence on Flies.—The police authorities c a town in Prussia are said to have issued a proclamatio against flies. The decree states that, inasmuch as fli contribute to the spreading of cholera, citizens are com manded to exert themselves to the utmost to destroy a flies within their houses. The proprietors of bee saloons are ordered to keep fly-catchers on their counter The penalty for not killing all the flies possible is a fir of $7.50 for each offence, and continued neglect t destroy them will be punished by imprisonment.

SOME OBSERVATIONS ON THE VIABILITY OF THE CHOLERA BACILLUS.[1]

BY EDWARD K. DUNHAM, PH.B., M.D.,

PROFESSOR OF HISTOLOGY AND BACTERIOLOGY IN BELLEVUE HOSPITAL MEDICAL COLLEGE; DIRECTOR OF THE CARNEGIE LABORATORY, NEW YORK.

DURING the autumn of 1886 and until the middle of 1887 I had opportunity to study the cholera bacillus at the Hygienic Institute in Berlin, which was then under the direction of Dr. Robert Koch. The work which he gave me to do was the comparison of cultures of different ages and from different sources. After completing that comparison I made a number of experiments to determine the length of time that the cholera bacillus would live when placed on various substances, and under various conditions; thinking that the results might be of some value in throwing light upon the way in which cholera might spread from place to place during an epidemic. These experiments I did not publish at the time, feeling that they were too fragmentary to warrant the deduction of any general conclusions as to the mode in which cholera spreads.

1. **In Agar-agar Cultures.**—On December 12, 1886, I received ten old agar cultures, from various sources, which had been prepared in 1885, and which had been reserved at the ordinary room temperature. From three of these cultures I succeeded in obtaining living cholera bacilli.[2] The cultures were started March 8, 1885, April 12, 1885, and June 5, 1885, respectively, showing that it is possible for the cholera bacillus to retain its viability in a single agar culture, without transplantation, for 681 days; one year, ten months and ten days.

Four agar cultures which had been in an incubator since February 19, 1885, were examined on January 3, 1886, in the same manner as the ten cultures already mentioned. Of these, one culture yielded living cholera bacilli—showing that cholera *may* live in agar culture 318 days at a temperature closely approximating that of the human body.

2. **In Fecal Matter.**—Four experiments were made with mixtures of fæces and cholera, and the mixture examined daily for living cholera bacilli. In no case were they found after the sixth day. The difficulty of finding the cholera bacillus in such a mixture increases with the age of the mixture, so that the failure to find them on a given day cannot be taken as proof that there are none present. When, however, as in these cases, a rapid diminution in the number present in equal bulks of the mixture examined from day to day is observed, and afterward, for a number of successive days, none can be found, the presumption seems reasonable that the bacillus gradually dies out and is no longer present in a living state soon after all efforts to detect it, fail.

The details of these four experiments are as follows: To two bouillon cultures of cholera in test-tubes large quantities of human fæces were added and, after thorough mixing, plate cultures were made in order to determine the relative abundance of cholera bacilli. It was found that the latter were relatively so numerous that the plate cultures resembled those made from a pure bouillon culture of cholera. Of these mixtures one was placed in an incubator at about 37° C., the other was kept at the temperature of the room. The mixtures were made March 25, 1887. On each succeeding day, for twelve days, plate cultures were made from the mixtures and the relative number of cholera bacilli determined. The mixture in the incubator showed an enormous decrease of cholera after twenty-four hours, and after forty-eight hours none could be found, although plate cultures were made twenty-five times, at nearly daily intervals, up to and including May 7th.

The mixture kept at the room temperature showed constantly diminishing numbers of cholera bacilli up to the seventh day, when none could be detected, nor could any be subsequently detected although the mixture was examined seventeen times up to and including April 26th.

The third experiment was similar to the second, except that a larger proportion of fæces was used. The results were identical (disappearance on seventh day), although the examination was repeated twenty times and extended to May 7th.

The fourth experiment was made without the use of bouillon; fæces, urine, and cholera from agar cultures being made up into a paste-like mass and kept at the room temperature. The experiment was started April 10th, and plate cultures made on that day showed the presence of considerable cholera. On the 11th no cholera could be detected, nor was any found on examining the mixture eleven times on nearly successive days up to April 26th.

Urine inoculated with large quantities of cholera from agar cultures and kept at the room temperature, exposed to the air, showed the presence of living cholera bacilli up to and including the fifth day. On the sixth, ninth, twelfth, and twenty-fourth days no cholera could be detected.

Stale urine, seven days after its passage, inoculated with cholera from agar cultures apparently killed the bacilli within twenty-four hours, nor could living cholera-germs be found on the third, sixth, or ninth day.

Dirty water from a settling tank connected with the drains of the Hygienic Museum inoculated with cholera from agar apparently killed within forty-eight hours, no living cholera being found on the second, fourth, sixth, ninth, or twenty-fourth days.

Sewage of neutral reaction collected at the Berlin City pumping station, inoculated with cholera from agar and kept at the room temperature, contained living cholera bacilli after twenty-four hours, but after forty eight hours none could be detected nor could any be found on the first, third, and sixth day thereafter.

3. **In River Water.**—Nine experiments were made, in which water from the river Spree was inoculated with cholera bacilli and then examined from day to day to determine the presence and number of cholera bacilli in known quantities of the water. The water was not sterilized[1] before the cholera was added to it, and the conditions of the experiment were varied with respect to the access of air, agitation, and addition of water fresh from the river. These modifications will best appear in the details given below. In no case could living cholera ba-

[1] Spirillum Choleræ Asiaticæ (Koch).

[2] Large portions of the agar cultures were placed in tubes containing sterile bouillon and the latter placed in an incubator. The three bouillon tubes which became cloudy were then examined by the plate method of culture and the characteristic colonies of cholera, and only these, found. These colonies were composed of motile comma bacilli, single and in S-shaped pairs. From these plates gelatine tubes were inoculated, and the subsequent growth corresponded exactly to that of the cholera bacillus.

[1] Experiments with cholera bacilli mixed with water previously sterilized by heat yield very different results, but do not represent conditions likely to occur in nature.

cilli be found after the sixth day. These results must, of course, be taken with the same allowance as those derived from the experiments with fecal matter.

In addition to the above nine experiments, eight similar ones were made with the addition of fresh-water plants (chiefly *Elodea canadensis*) taken from one of the ponds in the Thiergarten. These last experiments were failures, owing to the presence of large numbers of a rapidly liquefying bacillus, which destroyed the plate cultures before any colonies of the cholera bacillus could have time to develop sufficiently for detection, even with the aid of the microscope.

The cholera used for these experiments with water was lightly scraped from the surface of agar where it had grown at the body temperature for about twenty-four hours. Agar cultures were selected in order to avoid introducing much nutrient material into the water along with the cholera bacilli. Five hundred cubic centimetres of Spree water was inoculated with large quantities of cholera and placed in a tall glass cylinder, which had previously been rinsed repeatedly with the water alone. The column of water in the cylinder measured about seven and one-half inches (19 ctm). A fine, continuous stream of air was forced through a glass tube to the bottom of the cylinder, so that the bubbles as they rose kept the water in constant motion and well supplied with air. This experiment was made in duplicate, and the results may be tabulated thus:

	Experiment No. 1.				Experiment No. 2.			
A	B	C	D	E	B	C	D	E
	Cubic ctm.			Per cent.	Cubic ctm.			Per cent.
1	0.02	267,300	13,365,000	100	0.005	48,960	9,792,000	100
2	0.04	153,120	3,828,000	28.64	0.02	48,988	2,449,400	25.01
3	0.1	52,920	529,200	3.96	0.01	86,184	8,618,400*	88.01 [8.89]
4	0.04	13,608	340,200	2.54	0.1	259	2,590	0.026
5	1	352	352	0.0026	0.2	110	550	0.0056
6	1	126	126	0.00094	2	20	10	0.00001
7	2	None	None	0	....	None	None	0
8	....	None	None	0	....	None	None	0
9	....	None	None	0				

* Probably an error in placing the decimal point. Instead of 0.01 c.ctm. there was probably 0.1 c.ctm. taken.

Column A gives the number of days which had elapsed since the cholera was introduced into the water; B gives the amount of water taken for examination; C gives the number of living cholera bacilli estimated to have been in the sample taken (really the number of cholera colonies on the plate); D, the corresponding number of cholera bacilli for one cubic centimetre of the water; and E, the percentage present as compared with the number after the mixture had been agitated for twenty-four hours, taken as a standard for comparison.

The third experiment was like the foregoing, but much less cholera was introduced into the water, it seeming possible that there might be substances produced in the mixture which interfered with the vitality of the cholera bacillus. The calculated number of living cholera bacilli per cubic centimetre were as follows: After twenty-four hours, 6,006; forty-eight hours, 1,560; seventy-two hours, 140; four days, none; five, six, seven, and eight days, none.

The fourth and fifth experiments differed from the three earlier ones in that there was no air passed through the mixture of water and cholera. The figures per cubic centimetre are: Fourth experiment—After twenty-four hours, 7,872,400; forty eight hours, 3,550,800; three days, 617,670; four days, 4,600; five days, 700; six and seven days none. Fifth experiment—Twenty-four hours, 1,940; forty-eight hours, results lost through too high room temperature; three days, 79; four, five, six, seven, and eight days, none.

Thinking that perhaps the addition of fresh water from day to day might increase the chances that cholera would maintain itself in the water, experiments similar to all the foregoing were made, with the modification that after the first forty-eight hours, one-fifth (=100 c.c.) of the water was removed daily from the cylinder, and an equal bulk of water fresh from the Spree was added. Four such experiments were made.

The details of these experiments follow.

Experiment 6.—Spree water inoculated with cholera from agar culture. Subjected to continuous stream of air. Started April 25, 1887. April 26th, cholera bacilli per c.c., 4,926,900. April 27th, cholera bacilli per c.c. 1,558,400; 100 c.c. replaced by fresh Spree water. April 28th, cholera bacilli per c.c., 196,000; 100 c.c. replaced by Spree water. April 29th, cholera bacilli per c.c., 1,450; 100 c.c. replaced by Spree water. April 30th, cholera bacilli per c.c., 25; 100 c.c. replaced by Spree water. May 1st, no cholera in 2 c.c.; 100 c.c. replaced by Spree water. May 2d, no cholera in 2 c.c.; 100 c.c. replaced. May 3d, no cholera in 2 c.c. Experiment discontinued.

Experiment 7.—Similar to foregoing in every particular with the single exception that no air was passed through the water. The experiment was started the same day. The corresponding figures are: April 26th, 13,038,640; April 27th, 4,286,500; April 28th, 1,799,200; April 29th, 7,200; April 30th, 185; May 1st, 2d, and 3d, none.

Experiment 8.—Similar to Experiment 6, but less cholera introduced into the water. Started April 25th; April 26th, 6,804; April 27th, 1,610; April 28th, 29th, 30th, May 1st, 2d, 3d, none.

Experiment 9.—Similar to Experiment 7. Started April 25th; April 26th, 1,086; April 27th, 96; April 28th, 29th, 30th, May 1st, 2d, 3d, none.

In all the experiments with Spree water the number of bacteria not cholera which were present was often very great; sometimes as many as 400,000 being present in 1 c.c.

During April, May, June, and July, 1887, I made a number of experiments to determine how long cholera when placed upon a variety of substances would retain its vitality. These may be briefly detailed as follows:

4. **On Textile Fabrics.**—No. 1. Flannel soaked in blood-serum mixed with cholera from an agar culture. Kept in lightly covered glass dish at the room temperature. Examined almost daily, by means of plate culture, for sixteen days. Living cholera found up to and on the ninth day; after that a contamination with rapidly liquefying bacteria rendered the examinations negative.

No. 2. Similar to No. 1, but old sheeting used in place of the flannel. Living cholera found on twelfth day; none found on 13th or 16th. Contaminating bacteria increased in number progressively from the beginning of the experiment, and rendered the detection of the cholera more and more difficult. The latter undoubtedly diminished in number after the first few days.

No. 3. Old sheeting soaked in soapy water (five per cent. of a saturated solution laundry soap added to tap-water). After drying dipped in bouillon containing cholera from an agar culture. Part of the cloth in loosely covered glass dish. Living cholera found after forty-eight hours. None on the sixth or seventh days. Other portions of the cloth exposed to rapid drying in the air. No cholera after forty eight hours and seventy-two hours. These experiments were repeated four times with identical results.

5. **On Fruits, Vegetables, etc.**—No. 1. Lettuce leaves soaked in bouillon containing cholera from agar culture. Lightly covered dish; room temperature. Living cholera found up to and including fifth day; none on sixth and seventh days.

No. 2. Cauliflower, cooked; similar to No. 1. Living cholera found on sixth day. Material exhausted.

No. 3. Same as No. 2. Living cholera found up to and including tenth day, when contaminating bacteria became so abundant as to prevent detection of cholera.

No. 4. Same as No. 2, except that the specimen was kept in an ice-box (average temperature 8° C.). Living cholera present up to and on the thirteenth day. Experiment stopped by contamination.

No. 5. Raw cauliflower. Lightly covered; room temperature. Living cholera on thirteenth day. Contamination.

No. 6. Raw cauliflower. Ice-box. Living cholera on fourteenth day. Contamination.

No. 7. Cooked cauliflower. Incubator, 36° C. Living cholera on third day. Contamination.

No. 8. Sliced cucumber. Lightly covered; room temperature. Living cholera found up to and on twenty-first day. None found on the twenty eighth day. Specimen used up.

No. 9. Similar to No. 8, but slice exposed to free circulation of air; room temperature. Living cholera found after forty-eight hours. None on third and fourth days.

No. 10. Green surface of a cucumber painted with a twenty-four hour bouillon culture of cholera, exposed freely to the air. After twenty-four hours surface was dry and wrinkled, no living cholera found No living cholera after forty eight hours.

No. 11. Cut surface of strawberry inoculated from agar culture. Lightly covered; room temperature. No living cholera after twenty-four and forty-eight hours.

No. 12. Strawberry dipped in bouillon culture. Lightly covered; room temperature. No living cholera after twenty-four, forty-eight, seventy-two hours.

No. 13. Raw onion, sliced. Lightly covered; room temperature. Living cholera found after twenty-four hours. None after forty-eight and ninety-six hours.

No. 14. Raw tomato sliced. Lightly covered; room temperature. Living cholera found after twenty-four hours. None on third day.

No. 15. Hot-house grape inoculated from agar culture. Living cholera found after twenty-four hours. None after forty-eight hours.

No. 16. Broken surface of a peach painted with bouillon culture of cholera. Living cholera found after twenty-four hours. None after forty-eight hours.

No. 17. Outside surface of a peach painted with cholera bouillon. Lightly covered; room temperature. Living cholera found after twenty-four and forty-eight hours. On third day the peach was covered with an abundant growth of mould.

No. 18. Duplicate of No. 17. Living cholera after twenty four hours. None after forty-eight hours.

No. 19. Same as No. 16, except that the fruit was freely exposed to the circulating air. Living cholera found after twenty four and forty-eight hours. None on third day. This experiment was duplicated three days later and living cholera found after twenty-four hours, but none after forty-eight hours.

No. 20. Greengage painted with bouillon culture. Exposed to the air; room temperature. Living cholera after twenty-four hours, none after forty-eight hours.

No. 21. Cut surface of apple inoculated from an agar culture. Lightly covered; room temperature. Living cholera after forty-eight hours, none after seventy-two hours.

No. 22. Raw cabbage. Cut surface washed with bouillon culture of cholera, exposed to air; room temperature. After twenty-four hours fifty per cent. of bacteria present were cholera; after forty-eight hours there were very few cholera bacilli living. On third day none were found alive.

No. 23. Similar to No. 22, but lightly covered. After twenty-four hours thirty per cent. of the bacteria were cholera; after forty-eight hours, twenty per cent.; after seventy-two hours, fifteen per cent. On the fourth day none were found.

No. 24. Cooked cabbage, moistened with bouillon culture of cholera, exposed to air; room temperature. After twenty-four hours, abundant living cholera bacilli; after forty-eight hours, a few; after seventy-two hours, none.

No. 25. Similiar to No. 24, but lightly covered. Up to and including the third day numerous living cholera bacilli were found. On fourth day the contamination with other bacteria was so abundant that the experiment had to be discontinued.

No. 26. A raw cabbage-leaf was painted with a bouillon culture of cholera and then inverted over another leaf but otherwise exposed freely to the air. Room temperature. Up to and including the third day living cholera was found in progressively diminishing quantities. On the fourth day none was found.

The foregoing observations show, that while most of the substances upon which the cholera bacillus was placed cannot be regarded as media suitable for the indefinite maintenance of the life of the bacillus they were not so unfavorable to its existence that they might not readily serve as vehicles for the distribution of the germ. It appears that the most destructive influence is exerted by other bacteria, which take possession of the substratum to the exclusion of the cholera bacillus. But by the time this has taken place such substances as are articles of food would no longer be regarded as fit for consumption.

ABDOMINAL SECTION FOR DIAGNOSTIC PURPOSES.

By CLINTON CUSHING, M.D.,

SAN FRANCISCO, CAL.

In the excellent book of J. Greig Smith, on "Abdominal Surgery," he says, in speaking of exploratory incisions of the abdomen: "No incision ought to be merely exploratory. The exploratory incision of the skilled surgeon is widely different from that of the tyro. Where the former will make a correct diagnosis in ninety-nine out of a hundred cases, the latter will fall over his tenth case."

However skilful the surgeon may be I do not believe he can make an accurate and correct diagnosis in more than nine out of ten cases of abdominal disease by any method of external examination, if we leave out of consideration cases of ovarian cysts and uterine fibroids. Therefore, I think that the author quoted is in error, and that his quoted statement should not be allowed to stand unchallenged.

In spite of the fact that great progress has been made in later years, there still remain a considerable number of cases of abdominal disease of a serious character, upon the nature of which equally skilful and intelligent surgeons will disagree. This statement applies to cases of obstruction of the bowels, to disease of the vermiform appendix, to affections of the liver and gall-bladder and of the kidneys, and to pus collections in any part of the abdominal cavity.

The real facts in many cases of ruptured extra-uterine pregnancy are only clearly made out at a post-mortem examination. Exploratory incision is looked upon by Mr. Smith as a serious operation followed by a trying illness. In my hands it has not proven so; the serious part is the disease that warrants the operation, and not the operation itself, for with due care and cleanliness there is not one chance in a hundred that any bad result will follow the opening of the peritoneal cavity for the purposes of diagnosis.

I would not have it understood that I am an advocate of careless or reckless work, but where the symptoms are grave and growing steadily worse, and the life is at stake, if the symptoms point to some obscure disease of the abdominal cavity there should certainly be no hesitation in clearing up all doubts by an exploratory incision, if there be strength and vitality left to withstand the slight shock that attends the opening of the peritoneal cavity. During the past few years a number of cases have come under my observation that warrant me in these opinions, and I select from among them a few typical ones by way of illustration.

Case I.—In November, 1888, I was asked to take charge of a lady from Austin, Nev. She was twenty-seven years of age; two children, youngest four years of

age. She had suffered for many years a good deal of pain in region of ovaries and uterus, and when I first saw her was confined to bed and had a temperature of 102° F. The symptoms were those of a mild attack of pelvic peritonitis, but a careful bimanual examination showed the pelvic organs to be freely movable, although tender to the touch. The uterus was retroverted. Under the use of opiates, rest, and hot water vaginal injections, and the free use of quinine, the symptoms mended, and at the end of a month the temperature was normal and she was allowed to get out of bed. The digestion was poor and she complained of a feeling of distress in region of stomach and liver. At the end of ten days the fever returned with increased violence, and the repetition of the treatment gave only negative results. Manifestly I had to deal with some serious malady, the nature of which could not be clearly made out. She was now much emaciated, and I advised an exploratory incision, giving as my reason that there was probably a small collection of pus in one or both Fallopian tubes.

Professor L. C. Lane saw the case in consultation and agreed with me as to the propriety of the abdominal section, and the operation was done on January 31, 1889. Upon opening the abdomen the tubes were found to be normal. I then enlarged the incision and introducing the whole hand began a systematic examination of all the abdominal organs. Finally I discovered on the under side of the liver a hard, rounded tumor firmly fixed, about the size of a turkey's egg. While manipulating it between the thumb and finger I found movable masses within, and at once concluded that I had to deal with an enlarged and an inflamed gall-bladder filled with gall-stones. I at once sutured the retroverted uterus to the anterior abdominal wall and closed the incision in the abdomen. I then laid open the abdomen by a free incision near the lower border of the ribs, and with the finger-tips loosened the adhesions of the gall-bladder from the surrounding structures, and drew it up and stitched it to the edge of the abdominal wound, laid it open, and removed a small handful of biliary calculi, leaving in the viscus a small drainage-tube for one week. The improvement was remarkable; the pain and fever immediately left her, and in six weeks she had regained her normal weight. A small biliary fistula remained for three months, which healed at once upon removal of another gall-stone which had been left in the bladder at the time of the operation, or had worked its way down from the ducts subsequently. The gall-bladder contained also purulent matter, and this, together with the local peritonitis, was doubtless the cause of the fever. The only symptom that would lead to the suspicion that such disease existed was the indigestion and the sense of uneasiness and pain in the region, but this was no greater than is often seen in those who have suffered from habitual dyspepsia. The external examination gave no clew, for the gall-bladder was firmly fixed high up under the border of the liver. One year after the operation the uterus retained its normal position and she remained in good health.

Case II.—Mrs. W. F——, aged twenty-four; one child, one abortion. Came to San Francisco from Honolulu in the summer of 1891, and for three months was under the care of two competent medical gentlemen, who treated her for some obscure and painful affection of the pelvic organs. But little good attended their efforts, and I was asked to take charge of the case. Upon examination the abdomen was found to be distended with gas and very tender on pressure. The uterus was moderately fixed, retroverted, and sensitive to the touch, cervix slightly lacerated, bladder irritable, and urination painful. Temperature, 105° F. A purge of ten grains of calomel was given, which acted freely, but without relief to symptoms. Manifestly there was some serious trouble in the abdominal cavity, probably a pyo-salpynx, and an exploratory incision was advised, and after setting forth the facts in the case, the plan was agreed to and the patient was removed to my private hospital and the abdomen opened. It was then found that the patient was suffering from general peritonitis. The vermiform appendix was enlarged, contained several small particles of hard fecal matter the size of small peas, and two openings or ulcerations existed extending from the cavity of the appendix into the peritoneal cavity. The appendix was slightly adherent to the adjacent structures by bands of lymph. The right Fallopian tube contained two ounces of pus. The appendix and Fallopian tube were ligated and removed, the abdomen washed out with hot water and a drainage-tube left in forty-eight hours. Recovery was uninterrupted, and she returned to her home on the twenty-first day following the operation. In this case there was no suspicion of disease of the appendix before the exploration, and had the operation been delayed she would doubtless have died promptly, whereas from the moment of opening the abdomen I was master of the situation and recovery was at once almost a certainty.

Case III.—On November 16, 1891, I saw, in consultation with Dr. B. F. Clark, a woman twenty one years of age, one child and one miscarriage, who was suffering from some obscure and painful disease of the abdominal cavity following an attack of pelvic peritonitis. From the history, symptoms, and examination it was concluded that it was a case of pelvic abscess, such a case as in former years I would have punctured through the roof of the vagina, but it was decided to make an exploratory incision and clear up all uncertainties. On the following day the plan was carried out, and in addition to a double pyo-salpynx we found near the umbilicus a mass the size of the closed fist, consisting of omentum and small intestines firmly aglutinated together. I began cautiously to break up the adhesions and dissect the various layers apart with my finger-nails, and in the centre of the mass I came upon an abscess containing two ounces of ill-smelling pus, the walls of which were gangrenous in appearance. The tube and ovaries were removed and the parts thoroughly washed, a drainage-tube inserted for three days, after which recovery was uninterrupted. In this case any procedure short of abdominal surgery would have been of little use.

Case IV.—On June 15, 1892, I was asked by Dr. Myers, of Union Street, to see a case with him. She was twenty-seven years of age, had been married ten months, and eight days before I saw her had suffered a miscarriage of six weeks' pregnancy. Following the abortion, fever developed, and when I saw her, her temperature was 104½° F. She was bathed in perspiration, the abdomen greatly distended, and the suffering intense. The expression of the face was the peculiar pinched, anxious look so familiar to those who have much to do with cases of abdominal surgery. Upon examination it was found that a large solid tumor of the size of a child's head occupied the pelvic cavity. An offensive discharge was escaping from the os uteri, and the uterine cavity measured six inches. An important question at once presented itself: Was the woman suffering from septicæmia due to absorption from a decomposing placenta, or had she already a general peritonitis from extension of disease along the Fallopian tube into the peritoneal cavity? If the former, the curetting of the uterine cavity might prove of service; if the latter, it would do no good. An exploratory incision was decided upon, and the following day I opened the abdomen, and at once found purulent general peritonitis and a large, sloughy looking uterine fibroid. During the examination pus was seen flowing freely into the peritoneal cavity from the free opening of the Fallopian tube. I at once tied off the broad ligaments, ligated the uterine arteries, removed the tumor, tubes, and ovaries, leaving the stump of the cervix closed in by flaps and a whip-stitch of cat gut after the method of Schroeder. The abdominal cavity was washed and drained, the temperature at once went down to 100° F., and there was but little shock.

The recovery was uneventful, except that the abdominal

ound did not unite, owing to the infection during the peration by the purulent discharge, and that in order to cure more perfect drainage on the fifth day I passed a bber tube from the abdominal wound through the stump the cervix into and out of the vagina. The patient as out of bed in five weeks, and walking about a week ter, having gained very materially in weight during her nfinement to bed.

With these facts before us, can there be any question the mind of any intelligent surgeon of the proper course pursue? Certainly, courage and prompt action are cessary if good results are to follow.

On July 26, 1892, an Italian woman, twenty years of e, was brought to my private hospital in a greatly ema- ated condition. Her temperature was 102° F., and pulse o. She had borne one child two years before.

Eight months before I saw her she had an attack which om the history I should judge was pelvic peritonitis, ce which time there had been steadily failing health d progressive emaciation, accompanied with much ab- minal pain, fever, and profuse perspiration. She had en having for several weeks a discharge of pus daily m the rectum.

A bimanual examination showed the pelvic organs nly fixed and tender, the abdomen not distended, and marked thickening at any point that would indicate a cumscribed pus collection.

With the assistance of Dr. B. F. Clark the abdomen s opened on the following day, and we found the peri- eum enormously thickened. The moment the cavity s opened a gush of pus occurred, and this was followed the discharge of fully three quarts of yellow and mous pus of very fetid odor. The sac was now washed with several gallons of hot water and the whole sur- e mopped over with a mixture of equal parts of com- nd tincture of iodine and carbolic acid.

An examination showed that the pus cavity extended m Douglas's pouch to the ensiform cartilage. No pelvic abdominal organs were anywhere in sight, all being ied in lymph and pushed in every direction by the roaching pus sac. Two drainage-tubes were fastened and every twenty-four hours the cavity was thoroughly hed out with a half-ounce of compound tincture of ine to a gallon of hot water. Rectal injections of skey and milk, and five grains of quinine every five rs administered by the mouth, produced a marked ect.

At this writing convalescence is fully established, with ry prospect of return to health. Had tentative sures been employed here, or some imperfect system drainage, I believe the result would have been disas- is.

There was no way of learning from the external ex nation of the great extent of the disease, and the der is that any human being could carry about such a dful load of filth and live.

t might be said that the cases reported are exceptional. nswer I would say that similar cases are coming under observation constantly, and every year adds strength he conviction that in properly selected cases explora- incision of the peritoneal cavity is one of the most uable additions to surgery that has been made in later s, and that when a patient dies after an abdominal ion the fault lies with the disorder that warranted it, not with the operation, providing, of course, that the ical work has been done properly and with strict ob- ance of cleanliness.

---

nture of the Lung has been carried out by Dr. Germonprez in a man of eighteen, whose pleura had n opened for a pyoneumothorax, and had been fol- d by a persistent broncho-pleural fistula. Portions x ribs were removed and the orifice of the fistula sutured with catgut. The patient made a slow re- ry, but finally was able to resume work.

TREATMENT OF CHRONIC ENDOMETRITIS.[1]

By S. L. ELSNER, M.D.,

ROCHESTER, N. Y.

UNTIL within about ten years ago our knowledge of the pathology of chronic endometritis—to say nothing of its treatment—was indeed meagre. Even in our larger hospitals no local treatment was carried on above the internal os. Everything of a catarrhal nature had its seat in the cervix, ulcerations were entirely local, and cervical catarrh a constitutional disorder requiring only tonic treatment. In fact, the uterus was not lined by mucous membrane in those days, and, naturally enough, was not to be treated as the mucous membrane of other cavities. We now know, however, that there is epithelium in the lining of the uterus, that it contains glands, and that these glands perform the function of other mucous glands. Why, then, is it that to day we find good practitioners who will insist that the uterine canal should not be treated locally? Almost all who have been treating this mucous membrane have deemed it sufficient to apply alteratives and caustics by means of a cotton carrier, which on reaching the internal os was entirely robbed of any medicinal properties, all of the solution being left behind the internal os and cervical canal to be swabbed out afterward with dry cotton. Naturally a chronic endometritis, by such treatment, was rarely ever cured, and when benefited the result unquestionably depended upon the frequent dilatation and improvement in the general constitution.

This constant tinkering with the interior of the uterus is certainly bad gynecology, and your patient, after months of treatment, is very little benefited.

Cases of endometritis, to be successfully treated, must be radically treated, and this does not mean that you are to give local treatment for six months. Have your patient enter an institution or keep her bed at home, and after preparing her as you would for any operation, administer an anæsthetic, wash out the vagina with 1 to 3,000 bichloride, and the uterine cavity with one-half that strength solution. Dilate the uterine canal with a steel dilator, curette the entire mucous membrane, and after swabbing it out with carbolic acid or tincture of iodine, drain the cavity.

No one here present will doubt the advisability of draining an organ that very likely is containing decomposing discharges.

The question, however, is, How are we to drain this cavity? If you will be careful to dilate the entire canal and not only elongate the cervical portion, the rest is comparatively simple. In cases of endometritis complicated by enlarged subinvoluted uteri there is no question of gauze being the best possible drain. This should be carried well up to the fundus and the vagina packed afterward. If, however, your uterus is not enlarged by subinvolution or other causes, it may be best to use a curved drain with one or more grooves to allow the discharges to escape into the dressings below. I prefer the hard-rubber drain in cases where you have a small uterus, and especially if that organ is not in proper position.

If you use gauze in these cases, you will find it a hard matter to keep it in place. It will often be rolled out into the vagina and so defeat your object in draining. The stem, on the other hand, will be easily retained by its bulb and the vaginal tampon. You can expect the result of such treatment, in carefully selected cases, to be very gratifying, and, in the majority of cases, you will get a permanent cure.

In selecting your cases you must exclude such as have pelvic cellulitis or peritonitis, cases of endometritis depending upon new-growths, and also those cases in which you already have tubular involvement. To operate upon such as these would be throwing oil on an already burning fire.

The following histories, taken from my case-book, illustrate the successful treatment of four cases:

[1] Read before Monroe County Medical Society, May 25, 1892.

Case I.—Mrs. Z——. First consulted me on April 16, 1890; aged thirty six; married ten years. One child, a boy of nine. This patient always enjoyed good health until six months after her boy was born. She noticed first that her menstruation was irregular and that the amount of blood was too large. This was followed by general pains, loss of flesh and strength, pallor, at times severe backache and bearing down. Two years ago the flow began to last two and three weeks, and was accompanied by pain and fainting-spells. In other words, she gradually became a chronic invalid. At the time when I first saw her she had been flowing for seven consecutive weeks. I found her very anæmic and in bed. Examination showed nothing abnormal excepting endometritis with subinvoluted uterus. She was given ergot for a few days prior to operation, and then after gradual dilatation, which I no longer practice, on April 24, 1890, I curetted her uterus and packed the whole cavity with iodoform gauze. She reacted well from the anæsthetic and gradually gained strength. She was given tonics and no local treatment whatever. Her menstruation followed at regular intervals, and she felt herself very well—to use her own terms, "a new woman." She afterward became pregnant, but miscarried during the ninth week. Since then she has had no trouble aside from the grip.

Case II.—Mrs. J. C. M——. First seen May 3, 1891. Married nine years. Two children and two miscarriages, the first miscarriage, two years ago, was instrumental. The second, six months after, cause unknown to patient. Since her second miscarriage she has had constant backache, dysmenorrhœa, and profuse vaginal discharge, her general health failing, appetite poor, and bowels constipated. Examination revealed bilateral laceration of the cervix, uterus slightly retroverted, profuse discharge from uterus, with erosion of entire cervix. She was given a few local treatments and told that after her next period she must have an operation. I explained to her that the uterus was to be curetted, and that later I would do a trachelorrhaphy. I saw no more of this patient until December, 1891 (seven months later). Her condition was somewhat improved, but the local symptoms were the same. Upon examination I found that she had had the laceration repaired, and the result of that operation was good. I prepared her for operation, and on December 16, 1891, dilated, curetted, and drained the uterus, using a stem. She was confined to her bed for four days, and to her room for several days longer, when I removed the drain. She had little or no pain in January and none since.

Case III.—Mrs. H——, aged twenty-two; married four years; two children, youngest one year old. Health poor during pregnancy, but after confinement felt better until she menstruated, five months ago. Amount large, lasting ten days; pain in both sides; backache with bearing down; appetite fair; bowels regular. Vaginal discharge well marked. Examination showed bilateral laceration, endometritis, erosion of cervix.

On February 22, 1892, I sent her to the Homœopathic Hospital, where I dilated, curetted her uterus, and did a trachelorrhaphy at the same time. I drained this uterus with iodoform gauze, not having a tube at hand, and I found that it answered all purposes, for the drainage was good. I removed the dressing on the fifth day, and the sutures on the fourteenth day, discharging her from the hospital on March 5, 1892. She has had two normal menstruations since, and gained fifteen pounds in weight.

Case IV.—Mrs. S——. First seen March 20, 1892; aged twenty-four; married seven years; has two children. Last pregnancy, two years ago, was complicated by adherent placenta. Her trouble dates from this last labor. Complains of profuse discharge, pains in loins, and back, with dysmenorrhœa. Examination showed uterus slightly enlarged and very tender, uterine sound enters $2\frac{7}{8}$ inches; pain upon passing instrument; marked uterine discharge. Operation April 4th. Dilated, curetted, and drained, using stem drain. Last menses, April 30th, lasted four days, very little pain. Patient was out of bed during this period and feels very well.

To conclude, I will but say: Be aseptic. Dilate the entire uterine cavity, and not only the cervix; curette thoroughly. Use a little tact in preventing pelvic inflammation and you will be delighted with your results.

MYELITIS FOLLOWING FEBRIS CATARRHUS EPIDEMICUS.

By L. L. VON WEDEKIND, M.D.,

UNITED STATES NAVY.

This case, which has been under observation for about eight months, and which presents a striking example of the peculiar sequelæ of "la grippe," occurs in a young man, twenty-five years of age, a soldier by occupation, a farmer during his earlier life, whose family history is excellent, and who denies absolutely ever having had syphilis, nor are any evidences of heredity or acquired syphilis present. Up to the time of his admission to the hospital he had enjoyed perfect health, never having had any sickness which he can recall.

On January 4, 1892, he was admitted to the United States Naval Hospital, at Chelsea, Mass., suffering as with catarrhus epidemicus, and while under treatment for this affection he developed scarlatina.

On January 18th convalescence was established, and up to February 16th this continued uninterruptedly, with a gain in strength, weight, and appetite.

On February 16th and subsequently, upon the slightest exertion patient would complain of much weakness, pain in legs and back, occipital headache, and profuse perspiration. An examination at this time revealed nothing abnormal as to heart, lungs, or kidneys, though patient complained of a præcordial pain and a feeling of constriction in the left chest. This præcordial pain has continued up to the present time, with intermissions of longer or shorter duration.

On February 21st he became very nervous, his condition anæmic, he began having night sweats, suffered from insomnia, anorexia, and marked asthenia. His urine has been frequently examined, and on all occasions found to be normal. Constipation obstinate.

On February 29th he developed symptoms of gastric irritation, which up to the present remains; and on March 22d the abdomen, in the region of the stomach, became hyperæsthetic. This hyperæsthesia has never abated, but is now more pronounced and of greater area. Headache, both frontal and occipital, has been an almost constant symptom. Temperature, since the establishment of convalescence from his original illness, has run a normal course, with a day or two of subnormal registration. Pulse, 55 to 70. Pupils dilated. Extremities cold and of cyanotic appearance, with muscular paralysis slowly progressing. Patient frequently complains of numbness and a prickling sensation in the legs and arms.

The hyperæsthesia of the spot on the abdomen has gradually enlarged from the size of the palm of a man's hand to the size of the hand outspread, following from the point of starting (the ensiform cartilage) a course outward, downward, and backward, along the border of the ribs and below, on the right side. The skin here is so tender that the slightest touch, the most gentle manipulation, causes exquisite pain, which is not increased, however, upon pressure being applied to the parts beneath. A zone of anæsthesia surrounds this location entirely, and the line of demarcation is well pronounced. There is, upon each endeavor to speak, a twitching of the lips, so marked as to render almost indistinguishable what is said.

The patient is utterly unable to retain any solid food, nor has he, since March 22d. When given to him, he may retain it for a few moments, but it is then thrown off with no attendant nausea, no pain—simply vomited, and causing thereafter no further trouble. This appears to

be a truly reflex action, the food acting as a foreign body, and ejected as would be an irritating substance in the larynx.

The insomnia has been one of the most prominent symptoms, and is to day as marked as it was in the earlier part of the illness. The cord seems to be involved in several different places.

When taking into consideration the uncertainty of the etiology of myelitis and the absence of a syphilitic taint or any one of the enumerated exciting causes of myelitis found in medical works), the presence of the patient in the hospital before and at the time of the ushering in of the attack, and the fact of his having suffered shortly before from "la grippe"—these facts lead me to suppose that this latter disease has caused the present state of affairs, and that the poison of, or that producing, febris catarrhus epidemicus, involving the nervous system in many cases, as it undoubtedly does, may affect the roots of the nerves, exciting inflammation, or may extend inward to the central nervous organs themselves.

A CASE OF SCORBUTUS IN AN INFANT.[1]

By WALTER LESTER CARR, M.D.,

NEW YORK.

Scorbutus in infancy is rare, and it is not always diagnosed when present. That it is found in infants whose parents are able to provide all the necessaries of life was shown in the able paper read by our Chairman before the American Pediatric Society.[2] The history I present is that of an infant, aged fifteen months, to whom the mother, an intelligent woman, gave the food, day after day, which caused the scurvy.

The infant was brought from Paterson, N. J., to the Children's Class at Bellevue Hospital, Out-door Department, and was under the observation of my assistants, Drs. Purdy and Newhaus; Dr. J. Lewis Smith also saw the case. The mother of the little patient had kept a careful watch of the symptoms, and her narrative is incorporated in the record.

V. R. K——, female, aged fifteen months, first child. The baby was nursed until she was six weeks of age, when she was weaned, and fed condensed milk for six weeks longer, after which Mellin's food was used. This seemed to agree with her, though at first she did not like it, and the condensed milk was given in its place from time to time. The first lower incisors showed at eight months; the baby stood and walked with assistance two weeks later. During September, 1891, bowel trouble developed, which continued for some months and weakened the baby very much. The diet was kept the same. In November she refused to stand, and when placed on her feet she would fall. The following month, December, she became irritable, fretful, and did not sleep well. She appeared to have fever. Her legs were tender and sore, and she kept her thighs drawn up on the abdomen. When her clothing was changed she would scream as if in pain. After this condition had lasted about six weeks the baby extended her legs, but did not seem able to use them, although they were not so tender. On the legs were streaks and spots which looked like bruises, and in the centre of some of the purpuric patches were reddish dots that resembled pin pricks.

The movements from the bowels were as frequent as sixteen a day, and varied greatly in appearance. Sometimes the stools were green, then were black, or dark green, and again were natural in color. Often they contained a large quantity of mucus and were streaked with blood.

May 18, 1892, I first saw the baby, and my attention was called to the weakness of her legs. I found her to be a plump infant, with very little muscular strength, and a great deal of tenderness over the body, and especially of the thighs. She evidently experienced pain when handled, and would begin to cry before she was touched. The thighs had a swollen appearance, and were sausage-shaped, with some of the swelling below the knees. The lower thirds of the femurs felt thickened, and the thighs were exquisitely tender. There was not any heat in the parts. The sensation was good, but the muscular power was so weakened that the extremities could not be drawn up. There were no stainings nor discolorations. The abdomen was soft and distended. The liver and spleen were not enlarged. As the baby cried the gums were seen to be swollen and bleeding, with the teeth half-hidden by the softened alveolar tissue. The tongue was covered with a dirty, yellowish-brown coating, and with blood from the gums.

The anterior fontanelle was as open as is usually observed at fifteen months. Head moist. No craniotabes. No marked rachitic changes in epiphyses, or along the edges of the flat bones.

Examination of the chest showed the presence of mucous râles, some of which at the bases of the lungs were rather fine; but there was no dulness. Temperature in the rectum was almost 105° F.

The mother was ordered to stop the condensed milk, and to give the baby fresh milk, beef-juice, and the juice of an orange every day. No medicine except a placebo was prescribed.

After the visit of May 18th the baby had measles, accompanied by a severe attack of bronchitis. The high temperature noted was no doubt due to the onset of the acute disease. Under the change in diet the baby had made rapid improvement, and although ill with the measles the gums were better in three days, and normal by the end of a week.

June 21st was recorded: "Baby's general condition good. Some perspiration of the head and body. The muscles are not very strong, and there is a slight curvature of the spine, due to the want of muscular support. There is no tenderness of the thighs. Gums are all right. The stools contain a little mucus."

June 29th the mother sends word that the baby's bowels are much improved, and that she is gaining in strength and weight. She uses her feet and legs better than she had ever done before the illness.

The history of the case shows that there were not any puzzling symptoms, and the diagnosis was readily made.

I wish to call attention to the two features that were most prominent, and which should be looked for in all cases of the same character. These symptoms were the tumefied bleeding gums, which almost covered the teeth, and the tender, swollen thighs.

6 East Fifty-eighth Street.

[2] Scorbutus in Infants, American Cases. By William Percy Northrup, M.D. Transactions of the American Pediatric Society, 1891.

Treatment of Burns.—Dr. Grange (*The Lancet*, August 27, 1892) finds that burns of the third and fourth degree are probably often fatal in young children when not a seventh of the body's surface is implicated. Since "shock" appears to be such an important factor, even when death occurs after the second day, the author believes the warm-bath treatment to be contra-indicated in those unaccustomed to baths, and that during the first forty-eight hours they tend to increase the shock. The great proportionate fatality in children may be partly explained, he thinks, by the fact that in them the shock to the nervous system, falling largely upon the medullary and emotional centres, expends itself upon parts essentially organic and of vital importance.

Ozæna may be cured, it is claimed, by the following simple combination, which Dr. Tarbau has employed successfully in ten cases: Iodol, tannic acid, and borax are to be mixed in equal parts and used as a snuff five or six times a day, and, as improvement goes on, three times daily.

Clinical Department.

CLINICAL HISTORY OF THE FIRST CASE OF CHOLERA IN NEW YORK.

By ROBERT DESHON, M.D.,
NEW YORK.

The man was thirty-five years of age, born in Ireland, and a resident of New York City for the past ten years. He was of dissolute habits and a hard drinker. His occupation was that of a plasterer and laborer, mainly along the river front.

He was taken sick on September 5, 1892, but previous to that date he had slight painless diarrhœa. On that night the diarrhœa increased in severity, causing him considerable annoyance. The following morning he arose feeling very weak, but well enough to eat a light breakfast and go to his work. At about 10.30 A.M. the diarrhœa became so violent, muscular debility and tremors, with a feeling of faintness, having been ushered in, that he was obliged to leave his work and go home. At 2.30 P.M. I was called to see the patient. I noticed that his face was pallid and had a very anxious expression, and nervous symptoms, such as tremors and vertigo, were very decided. The thirst was insatiable. There was also nausea and vomiting, with slight griping pains in the bowels. He had had about eleven stools since 10.30 A.M. His axillary temperature was 101° F., pulse irregular. The patient complained mostly of cramps in the muscles of the calves of the legs, arms, and fingers.

After prescribing and giving directions regarding the treatment, I left, feeling rather anxious about the case. At 8 30 P.M. I returned and found that the diarrhœa and vomiting had entirely ceased, and I was therefore unable to examine the excretions. At this time the patient's temperature was 97½° F., the pulse hardly perceptible, respirations oppressed and difficult, the tongue was dry and covered with a white coating, the hands and feet were cold and clammy, and covered with a slight moisture. All the symptoms of impending collapse were present.

The attendant informed me that the cramps in the abdomen had been so severe in the afternoon as to cause the patient to cry aloud. Knowing the case to be an important one, I called Dr. Henry F. Robinson in consultation. When we arrived at the house of the patient, at 9.15 P.M., we found him in a state of stupor, the whole body covered with a cold sweat, the radial pulse imperceptible, the eyes deeply sunken with dark rings around them, the skin shrunken and pinched, making the cheek-bones very prominent, and the rest of the body seemed to have assumed a bluish color.

After deliberate consideration of the clinical symptoms, we diagnosed the case as one of cholera asiatica. The man died about twenty minutes after we left the house.

Although we had neither of us ever seen a case of cholera asiatica before, the symptoms were such as would, without doubt, have puzzled almost any physician who had not seen such a case before. The fact that cholera asiatica was at the time prevalent in Europe and at the very entrance to our city, was an aid in diagnosing the case as we did. This, together with all the symptoms, appeared to us grounds for such diagnosis. The only facts unattainable were the source of infection, if any, and those resulting from an examination of the excretions, which had been disposed of in my absence.

Phenacetin is said by Dr. Green to diminish the frequency of calls to urination in elderly people, especially at night, and that ten grains at bedtime will often secure rest for those who habitually rise once or more during the night.—*Universal Medical Magazine.*

Hæmorrhoids rapidly diminish in size, become free from secretion and pain, and generally improve, according to Dr. James, if powdered daily with pure calomel.

TUBAL PREGNANCY.[1]

By WILLIAM PIERSON, M.D.,
AND
THOMAS W. HARVEY, M.D.,
ORANGE, N. J.

On August 23, 1892, at 10 A.M., Dr. Harvey was calle to see Mrs. H——, aged thirty-eight, an America mother of two children, the youngest ten years of age.

She had been well all night, but on rising from her be had been taken with a severe pain in the left side. Sh was lying on her left side with her limbs flexed and ev dently in a profound collapse. Her lips were blue an her limbs cold to the body. She was pulseless, e: tremely restless, and complaining of the pain in her al domen. She was able to answer questions, and said th she had missed her courses twice and had imagined th she had reached the change of life. However, she ha been flowing irregularly for the last two weeks.

Examination revealed a mass in the left side of th abdomen, immovable and dull on percussion. It wa situated above the pelvis, and was well-defined and i sensitive, although the patient was in such a feeble co dition that she hardly appreciated a painful touch.

The opinion was expressed that the condition was du to internal hemorrhage from the ruptured cyst of a extra-uterine pregnancy.

Dr. Pierson agreed with the diagnosis, and a laparo omy was accordingly proposed and made by him as soo as the preparations necessary for such an operation in private house could be made. The operation was mad with as much precaution as was possible under the ci cumstances. The abdomen was found full of fluid bloo and one large clot. These were rapidly turned out an the left Fallopian tube brought into view. It was e larged about the size of a black walnut, and presented rupture opening into the general peritoneal cavity th would admit the top of an ordinary lead-pencil. Th left tube and ovary were then removed, the abdome flushed out with warm boiled water, and the extern wound closed with silver wire and catgut. The patie was then given a copious enema of hot salt water an put to bed.

She made a good recovery, being able to sit up in chair on the fifteenth day, the abdominal wound bein entirely united.

On the fourth day the patient had two chills and sharp rise of temperature, which was attributed to stitch abscess that formed superficially at one of the si ver sutures. Evacuation of this was followed by com plete subsidence of the fever.

This patient's condition prior to the operation was on of most severe shock. She received between the tim that she was first seen and the time of operation, just tw hours and a half, 4 ounces of whiskey by the mouth 120 minims of whiskey, $\frac{1}{100}$ grain of nitro-glycerine, an ½ grain of morphine hypodermically, and during th operation she received 60 minims of whiskey hypoder mically; yet at no time did she react more than to hav a very feeble pulse at the wrist.

Within a half hour after the operation she was in bette condition than at any time previous.

Examination of the part removed showed that th ruptured tube had within its cavity an ovum of about si weeks, with the amnion still intact.

[1] Case reported to the Orange Mountain Medical Society, Septem ber 9, 1892.

Thermometric Observation.—"Mamma," said littl Johnny, "if I swallowed a thermometer would I die b degrees?"—*Boston Post.*

Professor Carl v. Rokitansky has been appointed Pro fessor of Obstetrics and Gynecology at the University o Gratz, to succeed Dr. Ernst Börner.

New York, October 8, 1892.

AN INVESTIGATION OF THREE ANTIPYRETICS.

THE following conclusions regarding antipyrine, phenacetine, and phenocoll are the result of a series of experiments made in the Physiological Laboratory of the University of Pennsylvania by Drs. David Cerne and William S. Carter. They are published in detail in *Notes on New Remedies*. The points studied were those the effect of the drugs on the circulation and on the thermogenic function. Taking first the subject of the circulation, it was found that antipyrine in small and moderate amounts produces a rise of the arterial pressure, this stimulating effect being due to an action upon the heart. The lowering of the pressure by large or toxic doses is due similarly to a depressant action of the drug on the cardiac organ. The remedy does not seem to influence the vaso-motor system. Antipyrine causes an increase in the pulse-rate through paralysis of the cardio-inhibitory centres. The secondary decrease in the number of pulsations is of a purely cardiac origin, the drug exercising a depressant effect upon the heart itself. Antipyrine, in excessive doses only, changes the hæmoglobin into the blood into methæmoglobin.

The conclusions regarding phenacetine were that in moderate doses it causes a rise of the arterial pressure by acting upon the heart, and probably likewise by a stimulating influence exercised on the vaso-motor system. The reduction of pressure by the drug in large amounts is mainly of a cardiac origin. The remedy increases in small doses the force of the heart by a direct action. Phenacetine increases the pulse-rate chiefly by cardiac stimulation, and possibly also by influencing the cardio-accelerating apparatus. The drug reduces the number of pulsations, especially in large quantities, primarily, by stimulating the cardio-inhibitory centres, and, later, by a depressant action upon the heart.

It was found that phenocoll, in ordinary amounts, has practically no effect upon the circulation. Large doses diminish the blood pressure by influencing the heart. Phenocoll reduces the pulse-rate by stimulating the cardio-inhibitory centres. It then increases the rapidity of the pulse by paralyzing said centres. The final diminution is of cardiac origin. Upon the blood itself phenocoll has no action.

Regarding heat phenomena the following conclusions are drawn:

1. Antipyrine, phenacetine, and phenocoll all fail to produce any effect on the heat functions of the normal animal.

2. Antipyrine produces a decided fall of temperature in the first hour after its administration in the fevered animal. This reduction is due to a great increase in heat dissipation, together with a fall in the heat production.

3. Phenacetine, both in septic and albumose fevers, produces a very slight fall of temperature during the first and second hours after its ingestion by the stomach, but the greatest reduction occurs the third hour after its ingestion. The fall of temperature results chiefly from a decrease in heat production, with a slight increase in the heat dissipation. The increase in dissipation is not as great as with antipyrine. Probably the delayed action of the drug depends on its insolubility.

4. Phenocoll causes in fever a very decided fall in temperature, which occurs the first hour after the administration of the drug by the stomach. This reduction is the result of an enormous diminution of heat production, without any alteration of heat dissipation.

The general conclusion would be that phenocoll produced less tendency to cyanosis, and was a better antipyretic because it lessens heart production. Phenacetine is safe so far as the heart is concerned, and it is known clinically that it is a superior analgesic. All of the three drugs, however, will produce cyanosis and cardiac depression if given in very large doses.

THE TREATMENT OF BALDNESS.

THE public always welcomes with eagerness anything that is new and hopeful pertaining to the treatment of baldness. While the hopes that may be thus raised are soon dashed to the earth by a few personal experiments, or the object-lesson of a consultation with eminent but thin-haired dermatologists, it is not wise to suppress the new discoveries; for science may yet triumph over alopecia as it has over even more formidable obstacles.

This much is certainly being done: baldness is being very richly classified, and its clinical manifestations accurately mapped out. Fournier gives us two groups and nine classes of baldness. That there are nine muses and nine kinds of baldness, is a fact full of suggestiveness and consolation to the poetic mind.

We shall not attempt to follow Fournier, or to go deeply into the etiology and remediology of alopecia. There seems to be a general opinion that, leaving out the post-infective forms, most kinds of baldness are neurotrophic, parasitic, or senile. For senile baldness we cannot expect a cure; the aged themselves accept their deciduousness as a part of the natural course of things. Of the other forms, Dr. A. H. Ohmann-Dumesnil, in *The Practitioner*, has a good deal that is hopeful to say. For the pre-senile or neurotic baldness he advises the following pill, taken twice daily: ℞. Strychniæ sulph., gr. $\frac{1}{60}$; ferri redacti, gr. j.; quiniæ bi-sulph., gr. j. To this he adds: hypophosphites and gr. $\frac{1}{8}$ to gr. $\frac{1}{6}$ of pilocarpine hydrochlorate at bed-time. For the parasitic forms of alopecia areata, Dr. Dumesnil advises a three per cent. solution of creolin for the entire scalp, and locally an ointment composed of hydrarg. perchlorid. corrosivi,

gr. j.; lanolini, ʒj. A more drastic measure, which he recommends for alopecia areata, is one first suggested, we believe, by Dr. L. Duncan Bulkley. It consists in painting the affected area with pure carbolic acid. This application Dr. Dumesnil applies twice a week, with results which he asserts have so far been uniformly gratifying.

FEMALE INEBRIATES AND SPECIAL LEGISLATION.

The law is a curious and wonderful thing, and becomes more so from year to year in the great commonwealth of New York.

The last embodiment of Democracy and statecraft which met at Albany passed a law authorizing the legal commitment of female inebriates to a certain excellent Episcopal refuge in this city. The persons committed may be victims of alcohol, opium, or other narcotic. They are committed on the certificate of two physicians, approved by a judge, much as is the case of lunatics. But the curious fact is that only women can be committed, and these women can only be committed to the one private sanitarium.

The law is beneficent and beyond criticism so far as it goes, but it is a beautiful illustration of special legislation, concerning which the eminent predecessor of Governor Flower had much to say, and much to do. We only hope that there will next year be proper provision made for the unhappy male victims of inebriety.

ORGANIC AND SOMATIC DEATH.

A correspondent of the *British Medical Journal* asks if the hair ever grows after death. To this the editor replies:

"A question like this really hardly deserves a serious answer, although it comes to us from time to time from serious people. The unshaven beard of a dying man probably looks a little more prominent after death on account of the shrinking of the skin. The only recorded instance of which we are aware is that described by Guy de Maupassant in 'Belami,' his page 221. The French realistic novelist is supposed to hunt up "documents' for his facts, but we fear in this case the eminent novelist must have relied wholly upon his imagination in order to impress that of others."

Our esteemed contemporary is somewhat hasty in his judgment as to the above point. Cases in proof of the fact that the hair does grow after death have been reported by Good, Pariset, Villerme, and Bichat. The fact of the possibility of such growth is admitted by authorities in medical jurisprudence. It is not incompatible with the known laws of physiology, for these teach that we all have two deaths, a psychic or organic, and a somatic or cellular. Somatic life, *i.e.*, life of individual cells, may and probably always does continue for some time after the organs cease their work. A most extraordinary case of post-mortem growth of hair was reported in the Medical Record for August 18, 1877, by Dr. Caldwell, of Iowa. This gentleman was present at the exhumation of a body which had been buried for four years. He found that the coffin had given at the joints and that the hair protruded through the openings. He had evidence to show that the deceased was shaved before burial; nevertheless the hair of the whiskers measured eight inches and that of the head eighteen inches.

We are not prepared to deny that Dr. Caldwell was suffering under some hallucination, or had dug up the wrong man; but his evidence as to post-mortem growth of hair does not rest alone.

A GROWING EVIL.

We believe in wit and humor and poetry and all the *jeux d'esprit* that make the earth more lovely and lively; but we have no sympathy for the medical doggerel which clogs the columns of so many American medical journals. Listen to these sample verses which are going the rounds of some of our esteemed contemporaries:

> "We choose for a subject 'The Fever Typhoid,'
> An insidious disease people try to avoid.
> Its cause is a germ, wise men seem to think,
> Also most contagious through food and drink.
>
> "It attacks the whole body, the heart, lungs, and brain;
> The liver and kidneys are caught in its train.
> It strikes in the bowels, the peyerian glands;
> On the solitary ones its virus expands."

And so on for a dozen samples of pathology yoked to dysrhythmic verses. A corrective for such effusions was given by Mr. Pope some hundred odd years ago:

> "Hearken, ye wolves, while Ralph to Cynthia howls,
> And makes night hideous; answer him, ye owls."

THE TREATMENT OF RABIES BY IMMUNIFIED BLOOD-SERUM.

Experiments similar to those made in respect to tetanus have recently been carried out in the pathological laboratory of Bologna which would appear to show that blood-serum from a rabbit, rendered immune by the Pasteur method, will cure rabbits in an advanced stage of hydrophobia. And Professor Murri, of the Bologna University, has successfully applied the method to a human being already suffering from the disease. An account of the case and of the method is to be found in an original article translated by Dr. Hime in the *Lancet* of June 4, 1892.

Commenting editorially upon this important advance in treatment, this journal says that "Tizzoni had already proved, in conjunction with Schwarz, that the serum from the circulation of an animal rendered proof against the hydrophobic virus reveals a disinfectant action, destroying the said virus when introduced by inoculation in rabbits, and this for an interval of time of about forty eight hours. He next verified the validity of the doctrine laid down by Valli at the beginning of the century that the substance of the nervous system of rabid animals when subjected to artifical digestions, loses its toxicity and, moreover, when injected, that it acts like the medullæ of Pasteur, endowing the inoculated animals (always rabbits, as being more alive to the infection) with resisting power against rabies."

He now claims to have succeeded by special method in extracting from the medulla of a hydrophobic animal the vaccinating substance, deprived of its toxicity, which forms the active agent of the Pasteur treatment. The

stance, he asserts, invariably preserves rabbits from results of infection, but it will not cure the disease if n as late as seven days after injection. If, however, serum of vaccinated animals be employed instead of non toxic vaccinating substance, the "immunify-substance," already elaborated in the organism of the s-proof animal, is brought into direct contact with poison of rabies, and nullifies its action. "In other ds, the vaccinating substance remains inert when the ady is developed; the 'immunifying substance' enables o combat the poison in cases where hitherto interven-ot any kind has been unavailing."

PASTES FOR CANCER.

. hears so much of the knife and of drugs in cancer it is something of a novelty to meet with an article n an eminent and scientific physician arguing in favor austic pastes. Dr. A. K. Robinson, in the *Interna-l Journal of Surgery*, maintains that in epithelioma-tumors, during the earlier stages, and even when they of considerable size, the use of caustic potash will much better results as regards complete removal of lisease than can be obtained with the knife, provided same area of tissue is destroyed or removed in both ations. He is furthermore satisfied that from the f the caustic potash, and some of the other caustics, is formed in the tissues cauterized a toxalbumin h is destructive to the cancer cells, or organisms, if exist. Perhaps, he adds, it is the inflammatory ess alone that gives such good results in the primary r, but when one sees enlarged lymph-glands at a dis-from the primary tumor diminish in size after the rization it is difficult to avoid the view that such an must be acting.

chloride of zinc the writer says: This can be used in stick form, or in solution, or in a paste. It not destroy tissue so rapidly as caustic potash, and ises much more pain, which also lasts for a much r period. It destroys both normal and pathological , although not with an equal degree of rapidity, and most valuable agent in the treatment of epitheliо-In all the cases suitable for the use of the potash nc can also be employed, and, in the stick form, on unt of its slower deliquescence, and the ability to as a pointed pencil or arrow, it is much to be pre-l for some cases. A chloride of zinc paste is one of est means we possess in the treatment of cutaneous elioma, and has also been strongly recommended for nary cancer.

The use of arsenious acid in the form of a paste den's paste), Dr. Robinson says, we have an agent n a certain class of cases has given the best results from any treatment. Marsden's paste consists of parts, by weight, of arsenious acid and powdered , rubbed well together, and enough water is added ke a paste about the consistence of butter. The must be freshly made each time it is used. It is l upon muslin or rubber plaster in a layer about uarter of an inch thick, and firmly applied to the Marsden advises that it be not applied at one time rger area than one square inch; but the writer has d it to very much larger surfaces and has never seen any injurious effects. It is not suitable for cancer of the lip, or of mucous membranes, on account of the danger of poisoning by absorption. A study of its action on a tumor of small size will give an idea of the result obtained when the treatment is properly conducted.

Comparing zinc and arsenic, Dr. Robinson says: The effect of the chloride of zinc paste in twenty-four hours is the same as that of the arsenious acid paste in sixteen to eighteen hours; but the injury to the normal tissue is greater with the former than with the latter, consequently the Marsden's paste has a tendency to destroy the pathological tissue in a special manner in addition to the action of a non-elective injurious agent, which destroys pathological tissue sooner than normal, provided the action requires to be exerted for a period of time to produce destruction of tissue.

The "cancroin" treatment of Adamkiewicz, the aniline dye treatment of Mosetig-Moorhof, the thallin papain treatment of Granville, and the voltaic treatment of Parsons all seem to have made little impression on cancer therapeutics, and we are brought by Dr. Robinson back to the treatment of our fathers; and, we may add, of many successful quacks.

IS THE MILLENNIUM AT HAND?

But a short time ago we were treated to the spectacle of seeing the entire medical profession amazed, and the reading portion of the civilized laity set agog—particularly the prematurely superannuated individual who had indulged in pleasures early and long drawn out—by a statement from one of the greatest living physiologists, that he had made a discovery of a substance the injection of which beneath the skin resulted in rejuvenescence. The promised land with the fountain of youth was apparently at hand. It is unnecessary to say that that person was the savant Brown-Séquard, and the substance the much-laughed-at testicular essence. The reputation of the promulgator of this plan of treatment was such as to demand corroboration or denial from the scientific world, and the result was that within a short time a great number of valetudinarians were mustered into service, here as in other countries, but all to no avail. The most carefully conducted experiments with a fluid prepared according to the specific instructions of the originator were made, but even the most sanguine were unable to detect any change in those experimented on, except such as might be explained on psychical grounds, namely, a feeling of mental exhilaration and a bettering of bodily tonicity; but unfortunately these were evanescent and the cessation of the injections was the signal for their departure. A few more trials, and it was soon after seemingly relegated to innocuous desuetude by all except its distinguished originator. He has persevered and is still laboring on the subject, and every now and then he has something to say on the subject in his *Journal de Physiologie*. But the world at large, it is safe to say, has dropped it, and is willing to wait now patiently until the miracles of lengthening the days of man from the time-honored three score years and ten to a number equal to Methusaleh's is proven. But if this seeming air of neglect seems to have pervaded most of the members of the medical profession, we cannot help but remark that the pollen

has in some cases fallen on fertile soil, and the resulting newly produced anthers are now beginning to show themselves in the numerous articles published in the European medical journals of the beneficent results following the injection of "nervous matter," for instance, in diseases which we know, much to our sorrow, to be incurable. To mention one, Constantin Paul recently reported that he had treated three cases of tabes, and several cases of neurasthenia and other diseases of a different nature, by the subcutaneous injection of a solution made from gray matter, and he cheerfully informs us that the fulgurating pains disappeared, the gait improved, and in one case the reflexes returned. If this was a case of true tabes, it surely makes great draughts on one's credulity. But a more striking example still is reported by Bard to the Medical Society of Lyons, wherein he deposes that he has been treating a case of acromegaly by injecting a solution of the pituitary gland of the sheep, and great benefit has resulted. We know very little of acromegaly, but one fact associated with its progress is, that in all cases yet reported it is an incurable disease, and progresses gradually on to death. We may build theories innumerable as to its causation, and sift them down, as has been done, to some disturbance in the pituitary gland or in the thyroid, or both, but on what ground it can be suggested that injection of the essence of a dead pituitary gland of an animal replaces the function of a gland that is diseased, is not apparent unless indeed it be on the ground of similia similibus curantur. Still these observers report cases of such conditions, but they are chary enough to say that they have as yet observed only great relief and amelioration, but which in their opinion they believe to be permanent; which means, in other words, that the activity of the present disease so far as its individuality is concerned, is at an end.

The science of physiological chemistry has within the past few years opened up avenues of research which were, within the memory of the present generation, only dreamed of, and nowhere has it been more potent than in demonstrating to us the fact that many diseases are dependent on the absorption into the system of tox-albumins, be they leucomaïnes or ptomaïnes or what they will, in the nature of substances manufactured in the system from living or dead matter. And we know also that many of these substances, when taken or absorbed in sufficient quantity, will cause death; and, like analogous animal and vegetable substances which are alkaloidal in their nature, they have the property of producing a stage of excitation or exhilaration when taken in small quantities or perhaps for a short time; and to this and another largely contributive element, namely the psychical element, must we attribute the apparent beneficent results in the most of these cases. This last, the psychical element, is not to be descried. It is unnecessary to insist on its importance even to the merest tyro. Innumerable examples show its importance and seeming efficacy every day. If such is not the explanation of the results in these cases, it is surely owing to the profession by the originators of such plans of treatment, that they formulate a theory or a hypothesis on which the rationale of their plan is to be explained. And then it can be left to the axiom first suggested by Lewis, that "every discovery is a verified hypothesis" as to what its ultimatum shall be.

News of the Week.

The First International Congress of Gynecology was held in Brussels on September 7th, 8th, and 9th, Dr. Kuferath presiding. Sir Spencer Wells made an opening address. Over four hundred persons were present. The special topics for discussion were—"Pelvic Suppuration" "Ectopic Gestation," and "Placenta Prævia."

The Treatment of Cholera by injections of hydrogen peroxide is being much exploited by correspondents. One Dr. E. Lee states that he has treated twenty two cases, with only two deaths.

Another Analgesic has been put on the market. It is called agathin, and it is composed of salicyl and methyl phenylhydrazon. Its dose is about ten grains, and its sponsor is Dr. Rosenbaum, of Frankfort.

Another Medical Prince.—At the University of Edinburgh, the medical commencement was held during the first week in August. Among those who received the degree of Bachelor of Medicine was an Indian prince, Sir Baghvat Singh Jareja, the Thakore Sahib of Ghondal. He is said to be the first native prince of Hindustan to acquire that particular degree, or any other Scottish medical diploma. His subjects purpose to signalize this unusual event by erecting a statue to their ruler, in his capital in Ghoudal, in which the newly made medical prince will appear in the gown and hood of his degree worn over his full native costume.

Ownership of Prescriptions.—A recent trial in a Detroit court resulted in placing the ownership of prescriptions in the hands of the patient and not in those of the pharmacist. Testimony going to show that druggists everywhere regard the prescription as their rightful property was excluded, on the ground that the patient has the highest claim to the written formula.

A Medical Cabinet Minister.—Mr. Gladstone has given a ministerial appointment to Sir Walter Foster, M.D., of Birmingham, by promoting him to the position of Political Secretary to the Local Government Board. This is said to be the first time in British history that the honor of this description has befallen a medical practioner.

Educational Progress.—Over one-third of the established medical institutions of the country now exact four or more years of professional study and three or more terms of lectures as conditions of graduation; forty-five per cent. more require three or more years of professional study and three regular terms of lectures. That is to say, nearly eighty-three per cent. have complied substantially, with the resolution of the Illinois State Board of Health of July, 1887. Of the remaining seventeen per cent. all but two are Southern schools—the exceptions being the College of Physicians and Surgeons of Boston, Mass., and the Northwestern Medical College of Toledo, O.—*Indiana Medical Journal.*

A New Gynecological Operation has been devised by Dr. Duhrsen, of Berlin. Its object is the vaginal fixation of the uterus for the relief of retroversion.

Compulsory Physical Education.—The Legislature of Ohio has enacted the following law: "*Be it enacted*

General Assembly of the State of Ohio. That physical lture which shall include calisthenics, shall be included the branches to be regularly taught in the common ools in cities of the first and second class, and in all ucational institutions supported wholly or in part by ney received from the State, and it shall be the duty boards of education of cities of the first and second ss, and boards of such educational institutions, to make vision in the schools and institutions under their jurisdiction for the teaching of physical culture and calisthenand to adopt such methods as shall adapt the same the pupils in the various grades therein."

Peroxide of Hydrogen in Diphtheria.—Dr. Francis H. liams recommends the use of strong solutions of perde of hydrogen in diphtheria (*Boston Medical and gical Journal*). He concludes that the peroxide ydrogen has the unique and necessary quality of disgrating the membrane and thus rendering the bacillus essible. As it only attacks dead organic matter the lthy tissues are not lacerated, as is the case when menical means are used to remove the membrane. The l peroxide of hydrogen solutions are an effective nicide against the bacillus of diphtheria, and not toxic he patient. The syringe is simple in construction inexpensive, it can be kept perfectly clean, and is attacked by solutions which quickly corrode metals. h it one can easily reach all parts of the throat which to be seen without a mirror. He adds that any local tment to be efficient must be applied early, and at uent intervals, but the strong peroxide solutions must be applied by the physician himself. They cannot roperly used by the relatives or attendants. During first few days, therefore, this takes more of the phy-n's time than otherwise, but the course of the dis- is much shortened in suitable cases, that is, where patient is seen early, and the membrane is accessible. point is to concentrate the attack before the patient oisoned, and thus save him from a prolonged illness. d nursing and proper and sufficient nourishment are to be omitted.

egistration of Prostitutes has been the subject of est in New Orleans of late. The City Council is idering the expediency of passing an ordinance re- ng the registration and weekly examination of fallen ien.

New Local Anæsthetic has recently been isolated iesel from the leaves of the small-leaved cocoa-plant va. Liebermann has proved that this base is ben- ψ tropeine, which bears no relation to the cocaine p, but is chemically closely related to atropine. It lled "tropsin" for brevity. Professor Schweigger, erlin, after several months' experience with tropsin e surgery, reports that: 1. A three per cent. solution uces complete corneal anæsthesia more rapidly than ine. Iridectomy could be done painlessly two min- after putting three drops into the eye. 2. Anæsthests from three to six minutes for each instillation, no further prolongation can be produced save by a dose. 3. Mydriasis is absent, or but slight. 4. emia never occurs, but sometimes there is a passing t hyperæmia, and a little smarting unless normal saline solution be used as a solvent. 5. No injurious symptoms were ever observed. 6. In removal of foreign bodies, tropsin seems, from its quicker action, far preferable to cocaine. Dr. Silex, assistant in the Policlinic, has obtained similar results.

Suicides are peculiar in the methods which they adopt as well as in other ways. Dr. James G. Kiernan states, among other things (*Medical Standard*), that some suicides drop, like Mr. Wegg, into "poetry." One Chicago specimen left the following couplet:

> Here's a receipt for a popular suicide,
> Take twenty grains of potassium cyanide.

He was a photographer and sought a painless death. German maidens often soak matches in beer and leave the world with a libation to Gambrinus. "Rough on rats" and strychnine are astonishingly popular considering the painful death produced by them, and the ease with which morphine and laudanum can be procured. Suicide by poison and drowning are most frequent among women, since they disfigure least. Revolutionists, miners, and quarrymen often use dynamite. A Chicago lunatic convicted of the murder of a policeman at an anarchist meeting, blew his face off with a dynamite cartridge and thereby ensured what, in a sane man, would have been horrible suffering. Penalties could exert but little influence on most insane suicides. The mass of suicides are, however, affected by them. Wherefore a modification of the New York suicide law (by a clause giving the body for dissection) would tend to check the growing suicide rate in Chicago.

The Ontario Medical Journal is the title of a new monthly published at Toronto, and edited by Drs. R. B. Orr and W. H. B. Aikins.

Obituary.

J. H. DOUGLAS, M.D.

NEW YORK.

Dr. J. H. Douglas, died in Washington on October 1st. Dr. Douglas was one of the well-known specialists in throat diseases of this city. He abandoned his practice during General Grant's illness, and devoted his time exclusively for six months trying to relieve the General's sufferings. After the death of General Grant, Dr. Douglas, then broken in health, sought to renew his practice in New York, but it was not long before it was discovered that he was suffering from the same malady for which he had been treating General Grant. He went to Cuba to recuperate his health, but received no permanent benefit from the trip. His livelihood depended upon his practice, and after the loss of that he became almost destitute. For the last few years he has been in almost straitened circumstances, dependent on his daughter, who is a $900 clerk in one of the departments. Dr. Douglas was born in the village of Waterford, Saratoga County, and was graduated from Williams College in 1844. He came at once to New York City, and remained here ever since, practising his profession until his health gave way under the strain on his system of General Grant's case. While he was in Cuba, in 1886, seeking to recuperate his health, he was nominated to succeed ex-Senator Platt on the Quarantine Commission, but the nomination was not confirmed by the Senate, which was Republican. He was sixty-nine years of age.

Society Reports.

MEDICAL SOCIETY OF VIRGINIA.

Twenty Third Annual Session, held at Alleghany Springs, Va., September 13, 14, and 15, 1892.

H. Grev Latham, M.D., President, in the Chair.

Medical Examining Boards the Only Means of Reforming Medical Education.—Dr. Jacob Michaux, of Richmond, delivered the Annual Address to the Public and Profession. His main points were the absolute necessity for (1) preliminary academic examinations before admission to the medical schools is allowed, and (2) separation of the teaching and the examining departments. He suggested that the various State examining boards be made boards of health.

Tetanus.—Dr. Charles M. Blackford, of Lynchburg, was the successful competitor for the Hunter McGuire prize of $100 for the best essay examined by a committee of five Fellows appointed for the purpose. He defined tetanus to be an acute, infectious disease, characterized by tonic contractions of the muscles of mastication. The following were his conclusions: 1. Tetanus consists essentially of a tonic spasm of certain muscles, which have been thrown into a state of physiological tetanus. 2. This is caused by an abnormal irritability of the reflex centres in the medulla and cord. 3. This hyperæsthesia is the result of the physiological action of certain ptomaïnes, or alkaloids of decomposition, formed in the wound, and absorbed therefrom. 4. These ptomaïnes are the result solely of the growth of a specific bacterium called the bacillus of tetanus, or the "bacillus of Nicolaier. 5. Tetanus is, therefore, a toxic disease, caused by the infection of a wound by this specific bacterium or its products.

As to treatment, "An ounce of prevention is preferable to the pound of cure." At once explore the wound and clean it of all foreign substances with scrupulous care. Open the recesses of the wound and apply a germicide. Iodoform or aristol should be freely used because of their undoubted power to destroy the ptomaïnes—perhaps through the iodine they contain. Corrosive sublimate and carbolic acid remain our chief aids in rendering the wound surgically clean, and should be used first. the iodoform or aristol being used after disinfection, If tetanus occurs after this disinfection then the wound has been contaminated as a result of some omission or commission on the part of the surgeon. The prevalent idea that wounds of the hands and feet are peculiarly liable to be followed by tetanus is due to the fact that the hands and feet are more liable to become dirty and are more difficult to cleanse.

Should the attack commence, the first indication is to stop the formation of the ptomaïne. To do this the wound should be opened and disinfected by means of a solution of corrosive sublimate ($\frac{1}{2}\frac{1}{5}$ths or $\frac{1}{5}\frac{1}{0}$ths), by the use of which the shock incident to the curette or cautery is avoided. To avoid peripheral irritation as far as possible, the room should be absolutely quiet. The bedclothes should be light, and, if practicable, supported by a frame above the patient so as not to touch him.

The speaker mentioned a number of drugs that have been used with more or less success, but held that the chief reliance should be on physostigma. A third of a grain of the extract subcutaneously, or a grain by the stomach every two hours, is enough to commence with. The subcutaneous use of salicylate of physostigmine is a more elegant mode of administration, and by this means the pain and spasm which attend the effort to swallow are avoided. Tetanus antitoxine, discovered by Tizzoni and Cattani, has been used successfully hypodermically to cause immunity from the disease, even in highly susceptible animals. Even the blood-serum of these immune animals is antitoxic, and produces immunity against, and cure of, the disease. Tetanus antitoxine may be produced in a solid shape by adding alcohol to the serum of an inoculated animal, and evaporating *in vac.*. Schwartz relates the case of a boy, fifteen years of age, treated by him; and says that Gagliardi, of Molinel, treated successfully a severe case by hypodermic injection of one gramme.

The subject for the session of 1893 is "Obstruction to the Function of Micturition, and the Results." The offer is open to members of State Medical Societies of West Virginia, Virginia, and North Carolina.

Dr. Joseph Price, of Philadelphia, Pa., offered, for the session of 1893, a prize of $100 for the best essay, by a member of the Virginia State Medical Society, on "The History of Surgery and of Surgeons in Virginia," his native State.

On nomination, Dr. Price was elected an Honorary Fellow of the Society.

The President's Address was delivered by Dr. H. Grev Latham, of Lynchburg.

Vertigo.—The discussion on this subject was opened by Dr. E. T. Brady, of Marion. After remarking upon the nature of vertigo, in general, he stated that the causes were gastric, cardiac, cerebral, laryngeal, ocular, auric, toxic, epileptic, and essential. Laryngeal vertigo he regarded as another form of epilepsy, and believed that it would eventually be found that the toxic form was the most common. He believed that a far greater number of cases were attributable to nervous causes than to disturbance of the intra cranial circulation. There are three causes that might affect the nerves, namely, *a*, the direct mechanical or chemical effect of poisons, or imperfectly oxidized materials accumulating in the blood; *b*. pressures upon centres governing the equilibrium, and *c*, reflex, from acute localized inflammations, the equilibrial centres being disturbed by unusual impressions caused by the deflection from associated nerve-fibres. In speaking of the gastric form, he called attention to the fact that it was not accompanied with violent indigestion, but that digestion was prolonged, or delayed. This he regarded as the most common form. He called attention to the fact that deaf-mutes were free from vertigo, and seemed to infer from this that the sense of hearing enters largely into the causation of this condition. He omitted epileptic vertigo as being a form of epilepsy, and deserving a more detailed treatment than could be accorded it in such a limited space of time. He recommended cocaine locally in Menière's disease, and suggested the advisability of producing deafness in obstinate cases.

Dr. William C. Dabney, of the University of Virginia, after remarking that vertigo is often due to toxic principles in the blood, recommended small doses of one tenth grain of morphine, as affording temporary relief in some forms of renal vertigo especially. Of course the most important point in all these cases is to remove the cause.

Dr. Bedford Brown, of Alexandria, said that vertigo is not a disease, but rather the manifestation of disease, usually functional, sometimes organic, and then again of purely sympathetic origin. It may arise from morbid conditions of the circulation of the nervous system of the most opposite character. It often precedes death from post partum or other uterine hemorrhage. Some of the most violent types of vertigo are associated with the hysterical state. Alcohol and tobacco are fruitful causes of vertigo through their poisonous action on the brain and sympathetic system. Indigestion of a transient character and protracted dyspepsia, such as biliousness, cause sympathetic vertigo. Then we have an explosive form of vertigo due to blood poisoning, as seen during the progress of uræmia—coming and going in rapid succession. The therapy is as diverse as the causes are varied. Antiphlogistics, such as cathartics, and a simple diet, are demanded when vertigo is associated with plethora or congestive tendencies. In cases of high arterial tension, due to hypertrophy of the left ventricle, digitalis and

nitro-glycerine are of use. Iron and strychnine almost invariably relieve cases associated with anæmia. Full doses of valerianate of ammonium and bromide of sodium give prompt results in the hysterical and nervous forms of vertigo. For the vertigo of Bright's disease, nitro-glycerine ($\frac{1}{70}$th gr.) three times daily, with saline aperients and diuretics, are of service. Among the very best eliminant diuretics in these cases is diuretine or the salicylate of theobromine, in doses of two to five grains every two or three hours, in capsular form. In "bilious vertigo" acid fermentation and putrefactive action should be corrected by alkalies, and then hydrochloric acid, pepsin, strychnine, and bismuth subnitrate should be given. In nervous, feeble constitutions, pills of valerianate of iron, quinine, and zinc, produce admirable effects. When the tendency to vertigo is marked and persistent, the urine should be tested for albumin, casts, and sugar. The speaker had never seen a case of chronic nephritis or diabetes mellitus that was not accompanied with more or less vertigo.

Dr. Joseph White, of Richmond, remarked that aural vertigo accompanies such troubles of the ear as hyperæmia, anæmia, and apoplectiform troubles of the labyrinth (Menière's disease), which are usually associated with corresponding alterations in the brain. Ophthalmic vertigo is due to lack of co-ordination of the ocular muscles. Nasal vertigo has been reported by a number of authors, who assert that the intra-nasal changes by way of Meckel's ganglion cause localized vaso motor alterations and anæmia in the brain. But Dr. White believed all such cases to belong to the category of "aural vertigo." Charcot first used the name laryngeal vertigo to designate laryngeal spasm followed immediately by vertigo and loss of consciousness. A patient in apparent health is suddenly seized with a mild tickling or irritation of the larynx, which produces a slight cough. Obscurity of vision and dizziness immediately follow, and he falls into a state of complete unconsciousness of only a few seconds' duration. Ordinarily there are no premonitory symptoms, and no assignable cause. In mild cases unconsciousness may not occur. The semblance to epilepsy is such that some observers style it "laryngeal epilepsy." The laryngeal cavity rarely presents evidence of lesion, although some cases have seemed to depend upon a catarrhal laryngitis.

Dr. Joseph Price, of Philadelphia, remarked upon some cases of vertigo following prolonged hemorrhage, as in tubal pregnancy, neglected polypi, etc.

Mysteries of Medicine was the title of a paper read by Dr. Charles W. Cleaves, of Wytheville. He recounted many of the absurd practices and teachings of physicians of centuries ago, and of the charlatans of this generation; and closed with quotations from Whittier and others, describing the true physician of to-day.

Puerperal Fever.—In his paper on this subject Dr. R. L. Martin, of Stuart, spoke of the accepted idea that all cases of puerperal fever are due to infection per vaginam. He reported two cases: 1. A lady, the fifth day after labor, had a chill; temperature, 104° F.; pulse, 160; respiration, 40; suppression of lochia and vomiting. Intra-uterine irrigation, 1 to 3,000 bichloride solution, by means of a fountain syringe, and Chamberlain's intrauterine tube was used. In three or four hours the temperature became normal; pulse, 96. Irrigation was repeated for the next few days as a matter of precaution, and iodoform gauze applied around the cervix. This patient made a good recovery and had no rise in temperature after the second day. 2. Abortion at the fourth month; the reporter saw the patient two days after, when she had chill, fever, and offensive lochia. He found portions of the placenta in utero; these were removed with the curette, and an intra-uterine irrigation of bichloride of mercury (1 to 4,000) was used; iodoform was also applied to the interior of the uterus, a dose of castor-oil given, and vaginal douche of hot water ordered daily. This case also made a rapid recovery. Dr. Martin said that during the first years of his practice, with but little local treatment and relying on internal treatment, he had lost most of his cases. Since using the improved treatment he has had no losses.

Strangulated Hernia.—Dr. Martin also reported an operation for strangulated inguinal hernia of four days' standing. The wound sloughed on the tenth day, and fecal matter passed for three weeks by the artificial opening, which gradually closed, so that now the patient passes fecal matter per rectum, is able to do her housework, and is in good health.

Dr. Joseph Price, of Philadelphia, remarked that puerperal fever may be due to any of several causes. Even before gestation a small, hidden fibroid may be waiting in the uterus, as it were, for pregnancy to occur, in order that the fœtal kicks of quickening may bruise it and start up inflammatory action. Undoubtedly many such a patient is buried without a correct diagnosis having been made during life. Puerperal fever is not always an infection from the outside, and yet absolute cleanliness cannot be too much insisted upon in every maternity. Childbed fever is common enough over the whole world. An epidemic of it is now prevailing in Los Angeles. In Paterson, N. J., there were eighteen deaths from it during the past year. Either there is some other cause for the disease in these localities, or else there is something wrong about the nurses, doctors, surroundings, etc. Dr Price was of the opinion that no woman ought ever to die of childbed fever contracted by so-called infection from without. The practice of the gospel of cleanliness will prevent infection.

Irrigation of the Colon and Feeding per Rectum.—Dr. Edwin Ricketts, of Cincinnati, gave a short description of the colon, showing that the distance from the rectum to the ileo-cæcal valve was a little more than five feet. By means of the Langdon rectal tube, which is five feet in length, the colon could be thoroughly irrigated with warm water. He reported cases in which he had fed by injecting nutrient enemas through this tube by means of the Davidson syringe, depositing the same between the ileo-cæcal valve and the rectum. The patient is thus less liable to lose the nourishment as when it is simply deposited within the rectum.

What Shall be Done with the Imbecile?—Dr. Samuel J. Fort, of Ellicott City, Md., reviewed the work of caring for that class of defectives as instituted by the elder Seguin, Richards, H. B. Wilbur, and others, gave some very interesting figures regarding the total number of idiots in the United States as reported in the census of 1890, and concluded with a plea for State provision for imbeciles of all grades in every State of the Union.

Common-sense in the Treatment of Discharge from the Ear.—Dr. Alexander Duane, of New York, presented a paper with this title. After enlarging upon the importance of the subject to the general practitioner, he contended that the therapeutic principles to be enforced here are the same as those governing the treatment of suppuration anywhere else, and are comprised in the words cleanliness, drainage, and the removal of hopelessly diseased tissue. These indications are best fulfilled by thorough irrigation with some cleansing fluid, the best one for the purpose being a weak solution of common salt. Politzeration to force out the residual discharge may be used as an adjuvant to the syringing. If these measures do not suffice for a cure, astringent powders (boric acid, alone or combined with zinc oxide) may be used, but only in connection with thorough cleansing by preliminary irrigation. Granulations and polypi must be carefully removed, the operation being done by a good light and with the patient fully under control. Any tendency of the granulations to recur must be checked by the instillation of alcohol with or without the addition of corrosive sublimate. In the case of caries, iodoform is useful. These procedures, combined with suitable constitutional treatment, will usually succeed unless there is extensive caries, or unless drainage is prevented by the

situation of the disease (in the attic) or by inflammatory hypertrophy and swelling. In this case resort should be had without delay to removal of the obstructing and diseased parts by a radical operation. By following out the treatment thus outlined the author believed that in nearly every case of chronic suppuration the disease can be cured, the danger of cerebral involvement be averted, and the necessity of doing a mastoid operation be done away with altogether.

Modern Electrical Methods as a Substitute for Surgery in Certain Pelvic Affections.—Dr. G. Betton Massey, of Philadelphia, read a paper on this subject. The conditions considered were diseased ovaries, fibroid tumors, and displacements. In spite of the wholesale castration of women for salpingo oöphoritis they rarely were in better health afterward, not only on account of the cutting of nerves and adhesions and other traumatisms produced by the operation, but because the primal seat of disease, the uterine inflammation, remained untouched. This condition preceded the catarrhal extension to the tubes, and in the writer's experience remained most important in most cases. Direct galvanic applications to the uterus were indicated, and would often result in the restoration of an unmutilated woman to society. Displacements were also now considered to be secondary effects of microbic infection, in spite of which the irrational treatment by pessaries continued. A reduction of oversize and weight, and restoration of muscular tone were here required, rather than the unnatural resort to a skeleton within the vagina; and in the accomplishment of this purpose well-considered intra-uterine applications of both galvanic and faradic currents were indicated. The author had treated sixty-eight fibroids by modifications of the Apostoli treatment, with good results in sixty-four cases. Seven had disappeared entirely, and the remainder of the sixty-four were reduced in size to various degrees, and were cured of hemorrhage, pain, and pressure symptoms.

Excision of the Female Breast.—Dr. Robert O. Owen, of Lynchburg, remarked that many growths within the female breast are, or if neglected will become, malignant. Painful enlargements of the breast, not ordinary abscesses, should be excised if the slightest disposition to malignancy presents. After describing the old method of operation, he reported a recent case to explain the method he now advocates as the best. Miss L——, aged nineteen, slight family history of cancer, had an ulcerated scirrhus of the right breast. Two semilunar incisions were made above and below and the growth was excised. After the flaps were drawn together at each extremity the wound was flushed out through the drainage-tube (still *in situ*) with a quart of warm Thiersch's solution. After this the tube was withdrawn, and the openings through which it had passed were closed, like the rest of the wound, by deep and close superficial sutures. The whole length of the incision was then painted with iodoform collodion. The oozing having been left uncontrolled, the entire cavity filled with blood. Thirty-six hours after the operation one deep and several of the close superficial sutures at each end of the wound were removed, and by gentle bimanual pressure the contained clot was expressed. The wound was then flushed with Thiersch's solution and injected with a small syringeful of the following:

℞. Aristol..... ʒ j.
Acidi boracici..... ʒ ss.
Ung. resinæ..... ʒ j.
Olei olivæ..... ʒ iij.
Acid. carbolat. (liquid)..... q. s. ad ʒ viij.
M.

The superficial stitches were removed on the sixth day, and the deep stitches on the tenth day. The patient went home cured on the eighteenth day. A principal point is to control hemorrhage by torsion. After separating the vessel from the surrounding tissue as cleanly as possible it should be caught at the end with a pair of Koeberle forceps and drawn out. The tissues should not be included. The special feature of this operation is perfect closure of the wound after cleaning and allowing the cavity to fill with oozed blood, as one's own blood is aseptic as regards himself. Dr. Owen did not approve of losing time in trying to control the oozing with hot water, etc., but believed the method described to be the surest and quickest.

Bacteria and Disease.—Dr. Charles M. Blackford, Jr., of Lynchburg, read a paper with this title. Bacteria affect the human system in many ways: 1. The bacterium directly attacks and destroys the tissues in which it lodges; thus in inflammations followed by pus formations pyogenic bacteria are probably directly responsible. 2. A by-product of the life of the micro-organism is the agent that immediately does the damage. Thus, in tetanus, the active poison is an alkaloidal product, or mixture of such products, resulting from the life of the bacillus tetanus. The alkaloidal products may be isolated, and are as certain to produce tetanus, if introduced into the system in sufficient quantities, as morphine is to produce its physiological effects. 3. Some bacteria are pathogenic only at times; under some peculiar environments they acquire malignancy. 4. Conversely, some bacteria that are naturally violent and malignant become attenuated in unsuitable media, so that inoculation produces only a mild type of the disease.

In order for it to be regarded as the cause of a disease the suspected bacterium must fulfil the following conditions: 1. It must be present in all cases of the disease. 2. It must not be found in the body except during the course of the disease; but this condition must be liberally interpreted, for there are conditions under which the same bacterium seems to be malignant at one time and not at another. 3. It must produce the disease when properly introduced into an animal susceptible to that particular disease.

Dr. Joseph Price, of Philadelphia, thought Senn's statement, that "at this time surgical pathology has almost become synonymous with surgical bacteriology," was rather too sweeping. Even Lister is not so enthusiastic over antisepsis as formerly. Too close following of the dicta of such teachers has often led to carbolic-acid poisoning in midwifery. The whole ground is covered by adopting the "gospel of cleanliness"—absolute cleanliness; and simple pure water is all sufficient. The speaker did not deny that there was some virtue in chemical surgery; in fact, chemical cleanliness will aid the surgeon; but it must not be carried too far, or it will impair the healing quality of the divided tissues, or even may fatally poison the victim. If cleanliness were maintained, Dr. Price would not dread germs except in the dressing. He had no confidence in the paraphernalia usually sold by surgical-instrument dealers; for, as a rule, they sell goods that have been handled many times by doctors who have wished to examine the stock. Dirt, whether under the finger-nails or about the dressing, is injurious.

Dr. L. G. Pedigo, of Roanoke, defended Listerism. Of course Lister went too far at first; but progress comes by stumbling and correction. It took Lister fifteen years to get professional attention directed to antiseptic surgery; but now, with its improved methods, it has come to stay its general principles are established. Germs cause suppuration and destruction of organic tissues; but chemical agents are sufficient to destroy them. He thought Dr. Price went too far in his claims for aseptic as opposed to antiseptic surgery. In fact it could hardly be called even aseptic, since he trusted to Philadelphia hydrant water for washing his wounds, boiling only a part of what he used. Yet if the report of the health officers of that city be true, that water is notorious for its impurities.

Dr. Thomas J. Moore, of Richmond, said the medical press has of late been too radical in its advocacy of asepsis, when in truth surgical practitioners of to-day are modifiers—are trimming off the angular points which

misshape the truth. Ten years ago a distinguished surgeon said that the doctrine of bacterial effect in surgery had come to stay only a few years, and it appears now that he was a prophet.

Dr. G. Betton Massey, of Philadelphia, stated that he had been a believer in the germ theory for years, and his convictions were so strong that he would think himself a murderer if he did not conduct his practice on this basis. Indeed, it is clear that the small minority of the profession who still say they do not, really do believe in germs. This is shown by the fact that they boil the water in which they keep their instruments. They say they do it to get rid of the "filth"—why not say "germs," or "bacteria?" Their acts speak louder than their words.

Dr. S. T. Earle, of Baltimore, Md., said that much of the discussion seemed to be simply on a matter of difference in the means employed to secure the same results. For example, one of the previous speakers sterilizes his ligatures in hot water in advance, and leaves them in the abdominal cavity, to be digested or absorbed, without risk; whereas, if he sterilized them by certain chemicals, they might not be absorbable. The important point in undertaking any operation is to decide what is and what is not obnoxious material to be used in the wound.

Dr. Price remarked that exceptionally few wounds unite if all the germs are destroyed. On one occasion he had to excise both mammæ on a woman—both being alike in size and condition. He determined to try chemical antisepsis on one and simple cleanliness with soap and water on the other breast. The side on which he used antiseptic dressings was slower in getting well than the other, which he dressed simply with occlusion pads, etc.

Dr. Blackford closed the discussion by saying that Dr. Price had discussed practice—not principles. The whole principle involved—whether by antiseptics or asepsis—consists in the effort to neutralize what Dr. Price refers to term surgical filth, but which is generally included under the head of bacteria.

A Successful Case of Colectomy for the Closure of an Artificial Anus was reported by Dr. Samuel T. Earle, of Baltimore, Md. The method used in the operation was that recommended by Dr. William Halsted, of the Johns Hopkins Hospital, which was found to be very satisfactory. The patient made a good recovery. The chief point brought out by the report of this case was the fact of the great strength of the fibrous coat of the intestine, and the reliance that can be placed upon it in all cases where it is necessary to suture the intestine, without resorting to plates or any foreign substance to strengthen the union.

Injuries of the Knee.—Dr. M. W. O'Brien, of Alexandria, read a paper entitled: "Injuries of the Knee: Their Treatment and Results. With Special Reference to the Prevention and Cure of Suppurative Action in and about the Joint." He thought it should be a surgical axiom, with reference to treatment of every wound of or near the knee joint, and of every congestive or inflammatory condition of that joint, that absolute rest by fixation should be given the entire limb from the body down. If serum is effused into the knee-joint cavity, draw it out antiseptically, and then elevate the foot, and put the entire limb up in plaster—the Bavarian dressing being the best—with the leg straight. This plaster dressing makes both extension and counter-extension, securely locks the joints, hold every muscle firmly but gently in its place, and puts the reflexes to sleep. He said that a knee-joint injury should never be dressed in a flexed position. This was contrary to the views of many surgeons; but experience and results prove that a flexed anchylosed leg is a nuisance, particularly so if the flexion is great. With fracture in a straight position perfect rest is secured. If pus forms, lay the joint widely open, wash the fluid out thoroughly, put in drainage tubes, and flush everything out as often as may be necessary with corrosive sublimate water, and improve the general condition of the patient by food and the use of quinine.

Acute Inflammatory Ear-ache.—Dr. John Herbert Claiborne, of New York, read a paper on "Acute Catarrhal Otitis Media." He placed his confidence in the following plan of treatment: 1. Hot ten per cent. solutions of cocaine instilled into the outer ear, retained from five to ten minutes. 2. Hot solutions of boric acid instilled into the outer ear, while spongio-piline soaked in hot water is applied over the whole ear surface. 3. Inflation by the bag and by the continuous method with the Eustachian catheter. 4. The administration of a drastic dose of Epsom salts. This he also uses as a systemic remedy.

After the acute stage is passed, blisters behind the ear may be useful, but do no good during the acute stage.

Gonorrhœa in Women.—Dr. George Tucker Harrison read a paper on this subject. Credit must be given to Noeggerath for first drawing attention to the serious nature of this disease. Experiments and investigations coinciding with clinical facts go to prove that all the secondary inflammatory processes, whether in the tubes, ovaries, peritoneum, or in the broad ligaments, not only may be produced by the gonococcus of Neisser, but in fact are so produced. He asserted that, with few exceptions, the wife of a man who prior to matrimony has been the victim of gonorrhœa, will sooner or later develop some form of the disease. He asserted further, that ninety per cent. of the causes remain uncured, and that of a hundred women who marry men who have had this disease, hardly ten per cent. remain healthy. He classified gonorrhœa in four groups: 1. Acute perimetritis; 2, recurrent perimetritis; 3. chronic perimetritis; and 4, ovaritis. Microscopic examinations have proven the existence of gonococci in pus taken from diseased tubes, and it is generally conceded that most of the inflammatory conditions of the tubes can be traced to this disease. Bumm denies this, and claims that the gonococcus of Neisser is only able to penetrate "cylindrical epithelium." But others state that it is capable of penetrating even striated squamous epithelium. As to treatment, prophylaxis naturally claims first and careful consideration. Dr. Harrison thinks it hardly possible to stamp out this disease. But that the general practitioner can correct the evil to a large extent. The gynecologist should be careful in dilating the womb of a woman who is affected with gonorrhœa, as the disease is so easily carried into the uterine cavity, thence into the tubes, etc.

Hypnotism as a Therapeutic Agent was the title of a paper read by Dr. William Lee Howard, of Baltimore, Md., in which he spoke of its uses and abuses, concluding with the recommendation that laws should be enacted to prevent the practice of hypnotism except by regularly licensed responsible physicians.

Sexual Hypochondriasis and Perversion of the Genesic Instinct.—Dr Irving C. Rosse, of Washington, D. C., read a paper with this title. Omitting reference to such subjects as spermatorrhœa, venereal excesses, malformations of the genital organs, and the high degree of excitement often found among the insane, he limited his paper to the consideration of the manœuvres of either sex to produce venereal orgasm independently of the conditions of normal coitus, and known comprehensively as genital abuse. Of all hypochondriacs of either sex, those who refer their sufferings to the genital organs, such as the onanists, nymphomaniacs, syphilophobes, etc., are the most miserable. It is an error to suppose that aberration of the genesic instinct is confined to our species, time, race, or latitude. Bestiality or sodomy has perhaps existed from all time. Juvenal mentions that donkeys were much sought after by women. A quotation from Plutarch indicates that there were relations between animals and human beings—men and women—in the Latin Empire. In our day this crime is less prevalent, though far from rare in large cities. The speaker mentioned numerous instances of sexual perversion which had come under the notice of the police in various cities in this

country and Europe. A study of these cases shows that the question of sexual perversion is one of social hygiene touching mental pathology in many points. Lawyers and doctors and juries want to know whether such cases are criminal in their nature or are the result of insanity. Physicians recognize that continuous suggestion, or the reading of lewd literature, or excessive indulgence in fondling embraces under improper circumstances, etc., do affect the lower lumbar reflexes in such a way as to bring about sexual hypochondriasis, not to mention their influence as wide disseminators of immorality and as teachers of crime. Many of the methods of societies for preventing vice and bringing about prohibitory legislation as to vicious literature, etc., though well meant, are both reprehensible and impracticable. Over-zeal leads to false philosophy and sophistry like that of the prohibitionist who would enact summary laws. The treatment of such cases of unnatural practices as have been referred to consists in prevention and education, with employment of proper medical and surgical measures. Self control should be inculcated, especially about the epoch of puberty. As an adjuvant nothing is better than gymnastic and athletic training. A verification of the judiciousness of this advice is often found in champion athletes, many of whom are temporarily impotent.

The Treatment of Hard Tumors in the Pelvis was the title of a communication presented by DR. JOSEPH PRICE, of Philadelphia. He advocated early treatment of small abdominal and pelvic tumors before real danger develops. Dermoid tumors especially require early attention.

One great danger of small, hard tumors, especially in the pelvis, is that they interfere with conception, and often with delivery. A dermoid on one side may bring on abortion after abortion, when the other side is entirely healthy, and so cause much useless suffering, both mental and physical. Hard tumors of the uterus, whether large or small, are accompanied with just such dangers as have been described, and the longer they are allowed to grow, and the more they are interfered with in a meddlesome way, the more dangerous do they become.

Long-continued Administration of Digitalis.—DR. F. M. BROOKES, of Fairfax Station, reported a case in which digitalis had been administered continuously from November, 1889, to September, 1892, the dose given being thirty-five drops of the tincture three times daily.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 13, 1892.

H. P. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

DR. GEORGE P. BIGGS presented the lungs from a man who had been admitted to the cells of Bellevue Hospital with delirium tremens, associated with a very high temperature, and signs of pulmonary consolidation of the lower lobes. The temperature reached 106° F. before death. The autopsy showed consolidation of both lower lobes of the lungs, having a somewhat lobular form, and a peculiar degenerated, cheesy appearance. Microscopical examination seemed to point to a lobular pneumonia. At the apex of one lung was a small cavity, about one centimetre in diameter, surrounded by a pigmented fibrous area of considerable extent. Scrapings from the surface of the consolidated portions were examined, and found to contain large numbers of tubercle bacilli.

DR. W. P. NORTHRUP said that the uniform distribution of the light spots seen in the specimen were very much like those so frequently seen in the broncho-pneumonia of children. From their distribution and general appearance he was inclined to think that the specimen showed a broncho-pneumonia with infiltration of the bronchioles.

Acute Yellow Atrophy of the Liver.—DR. BIGGS also presented gross and microscopical specimens from a case of acute yellow atrophy of the liver. The patient was a young woman, twenty-one years of age, who was admitted about 1 A.M. on April 8th, in a fairly rational condition, but unable to give a trustworthy history of her illness. She was found to be markedly jaundiced, the pulse was about 50, and the temperature 97° F. Physical examination showed the pelvic organs, and, in fact, all the other organs, normal excepting the liver, which was diminished in size. The jaundice became very intense, and she had frequent tonic spasms of the upper extremities and almost constant movements of the lower extremities, but not of a spasmodic or convulsive character. She passed gradually into a low form of delirium, then into a stupor, and finally into coma. The pulse remained slow until just before death, when it ran up to 130, and the temperature continued to be subnormal until just before death, when it suddenly rose to 105° F. The only special point of interest at the autopsy was the liver, which was markedly diminished in size, and weighed only thirty ounces. It was very soft and intensely congested, with the exception of a few slightly depressed areas, which were of a reddish color. Microscopical examination showed that there was an almost entire absence of liver-cells, and very extensive fatty degeneration, which was also present in the other organs.

Rupture of an Aneurism of the Abdominal Aorta into the Psoas Muscle.—DR. J. S. THACHER presented a specimen of this kind. The patient entered St. Luke's Hospital complaining of pain in the left side of the abdomen, and examination showed a tumor in the left lumbar and iliac regions, the nature of which could not be determined. Exploratory laparotomy was performed, and a pulsating tumor found in the iliac region. The patient died shortly afterward from acute peritonitis. The autopsy showed an aneurism pressing upon the first and second lumbar vertebræ, whose bodies it had eroded. Behind and to the right was an opening into the aorta, about one and a half inch in diameter. The left side of the aneurism had ruptured into the psoas muscle, and had extended inside of this muscle to a point about half an inch below Poupart's ligament. It had formed quite a large cavity in the muscle, which was found filled with blood-clots.

Sarcoma of the Kidney.—DR. H. J. BOLDT presented the above specimen. It had been removed from a woman, thirty-six years of age, a patient of Dr. Burke, who had presented herself to the speaker on January 4th, complaining of a pain in the lower and right hand portion of the abdomen, which had existed for about one year. She had had three normal labors. Examination showed a tumor, most prominent to the right of, and a little below, the umbilicus, and independent of the pelvic contents. A solid tumor of the right kidney was diagnosticated, and three days later the tumor was removed without difficulty by abdominal section. According to his invariable custom, the pedicle was tied with catgut. The peritoneum was closed over the cavity by a running catgut suture, no drainage being used. The other kidney appeared to be normal. The abdomen was then entirely closed, and the patient made a good recovery.

A Large Hydronephrotic Kidney.—DR. BOLDT presented a specimen which had been removed from Miss L——, a patient of Dr. Vandegrift, aged twenty-one. This patient began to menstruate when twelve years of age, the flow being regular and normal in quantity, but for the past seven years it had been preceded and accompanied by severe pain in the right ovarian region, which was also present in the inter-menstrual period, but was not so severe. Quite recently, also, there had also been pain in the right lumbar region. The bowels were constipated, and micturition frequent. She was poorly nourished, had a rapid, small pulse, and slight fever. Examination showed a tumor sensitive to touch, freely movable, and extending above the umbilicus, and it was thought to be an ovarian cystoma with a long pedicle, until an examination under anæsthesia, just prior to the operation, showed that it was independent of the ovary, and that it was

obably a tumor of the kidney. Abdominal section con-med this diagnosis, and showed so much destruction of is kidney, without any apparent involvement of the her kidney, that it was deemed advisable to remove is one rather than to simply drain it. The pedicle as accordingly tied with catgut, and drainage established rough the loin, and the peritoneum closed over the c, and the abdominal wound closed. With the excep-on of periodical elevations of temperature, which yielded omptly to the administration of quinine, the patient ade an uninterrupted recovery.

Dr. Boldt also showed specimens from two cases of arian cystoma, in which the condition had been mis-ken for pregnancy. One was a fibro-cystic tumor of e ovary, and the other an ordinary ovarian cystoma. bro-cystic tumors of the ovary are comparatively re. Both cases made uneventful recoveries after op-ation.

Removal of a Tumor of the Kidney from a Child Aged wo Years.—Dr. L. Emmett Holt presented a tumor the kidney which had been removed from a child aged o years. It had not been as yet examined microscopi-lly, but was probably a sarcoma. The patient had en under observation only three weeks prior to the op-ation, and the only history obtainable was that the elling had first been noticed in the right side of the ab-men, about six months before, appearing first in the re-on of the loin, and growing slowly. There had been pain or difficulty in micturition, and no such symptoms re observed after admission. The urine was repeated-examined, but with negative result. There was only derate cachexia. The tumor occupied the greater rt of the abdominal cavity, extending in the hypogas-c region nearly over to the left spine of the ilium, and owding the liver up into the hypochondriac region; it cupied almost all of the right side of the abdomen, was istic to the feel, and had a distinct sulcus in its centre, hich gave rise to some difference in opinion as to ether it was cystic or solid. The tumor was removed sterday by Dr. Abbe, through a lumbar incision. The eration lasted forty-five minutes, there was very lit-blood lost, and it was followed by very little shock. the present time the child is doing exceedingly well. out nineteen out of every twenty children operated for such tumors die within a few hours after the eration, from shock. It had not been necessary to sect any ribs in order to remove the tumor. The tu-or weighs two and one-quarter pounds, and appears to ve originated from the outer and anterior aspect of the lney. The ureter was patulous throughout.

Dr. Boldt said that some time ago, in removing a much ger tumor of the kidney from an adult, he had been mpelled to resect two ribs before he could enucleate e tumor.

A Safety-pin Impacted in the Œsophagus.—Dr. Holt sented a specimen from such a case. It had been re-oved from a child, aged nine and a half months, who d been under observation for a rather protracted pneu-onia, to which it finally succumbed. At the autopsy a fety-pin of small size was found impacted in the œsoph-s, about half an inch from the cardiac orifice, the ft of the pin lying along the œsophagus. It had pro-ced an ulceration of the œsophagus, and a certain ount of cellulitis. The pin was not corroded, it was g open with the hinge end downward, in the position which it was swallowed. As the ulceration was very superficial, it is probable that it had not been there more n ten days. There had been no symptoms referable this foreign body, except that, about ten days before ath, there was quite marked dyspnœa for a day or two h no obvious cause. This disappeared spontaneously, returned about eight hours before death, and continued il death. As the autopsy showed well-marked ca-rhal laryngitis, this may have been the cause of the pnœa. The child was able to drink well from its bot-up to within eight hours of death.

Stated Meeting, April 27, 1892.

H. P. Loomis, M.D., President.

The Diagnosis of Tumors of the Bladder by Microscopical Examinations.—Dr. F. Ferguson presented a series of specimens illustrating the different varieties of tumors of the bladder, their situation, and general characteristics, and dwelt particularly upon the important aid in diagnosis rendered by microscopical examinations. Exclusive of the cystoscope, he believed that the best method of making a diagnosis of tumors of the bladder was by continuous microscopical examination of the urine. This method of diagnosis is of comparatively recent date. The method which he adopted consisted in collecting the entire quantity of urine voided during the twenty-four hours, and collecting the sediment from this by filtration through cheese-cloth. Small fragments of tissue which are found in this sediment are hardened in alcohol, embedded in celloidin, and one or two hundred sections made and examined with a low power. If this preliminary examination reveals anything of importance, the sections are stained and examined with higher powers. In some cases a sufficient number of fragments may be obtained from a small quantity of urine, and may not require to be examined for several days at a time. The present method of removing a small quantity of urine with a pipette and examining one or two slides is very unsatisfactory, but by making repeated examinations of a large number of sections of tissue, much more valuable information can be obtained, and the speaker thought a more general adoption of this mode of examination would soon greatly enlarge our knowledge of tumors of the bladder. By this method he had made the diagnosis on several occasions, and had had the satisfaction of having its accuracy confirmed by subsequent operation.

Tumors of the bladder had, up to quite recently, been considered to be comparatively infrequent, and this was chiefly owing to the fact that at post mortem examinations the bladder is seldom subjected to the same careful examination as were the other parts of the body.

Dr. H. J. Boldt asked how long the diagnosis of these growths had been made in this way, for he knew that Dr. Heitzmann had been engaged in such work for a number of years. He would also like to know what precautions were taken to prevent the decomposition of the urine while the total quantity for the twenty-four hours was being collected.

Dr. Ferguson said that he supposed such examinations had been made only during the past twenty years, and then chiefly by German pathologists, who had reported occasional isolated cases. When speaking of the comparative newness of this method, he had referred particularly to the examination of small fragments, and the importance of making such examinations systematically. No special precautions were necessary to preserve the urine for twenty-four hours, as during this time it was not likely to undergo much change, and as the specific gravity of tumors was much greater than that of the urine—1.035 to 1.045—the fragments sunk to the bottom quickly, and were therefore quite easily collected.

Dr. Samuel Alexander said that he had been deeply interested in the paper, because he knew of no department of genito-urinary surgery where there is more need of such a contribution than in the pathology of tumors of the bladder, and previous writers had made very vague and confusing statements. He agreed with the author that this lack of accurate knowledge was chiefly due to the want of attention paid to the condition of the bladder at autopsies. It was certainly not to the credit of the profession that tumors of the bladder could grow to the size of those presented before any accurate diagnosis was made. Professor Guyon, in a paper read before the French Congress two or three years ago, said that it was the greater duration and persistence of the hemorrhage, in spite of rest and position, which was distinctive of tumor of the bladder; but such hemorrhages

are also present in the so called primary tubercle of the bladder, and in certain forms of chronic cystitis. Sufficient attention had not been called to the fact that operations were sometimes performed for supposed neoplasms in the bladder, when, in reality, the hemorrhage was due to certain fungous growths from the mucous membrane. Professor Guyon asks if these represent an early stage of villous growths, or if they are simply the result of inflammation, or due to the destruction of the mucous membrane in places, causing this appearance of villosities. The speaker said that the presence of vessels and cylindrical epithelial cells would seem to indicate that they are true villous growths.

The method described in the paper for the microscopical examination of the *débris*, is most excellent, but it would require long experience and close study before such examinations would yield us thoroughly trustworthy results. For instance, if the portions examined are from villous growths, nothing could be affirmed concerning the character of the tumor, as these growths often spring from the surface of other tumors. He had met with two cases where there were a number of such small growths, and microscopical examination made after the death of these patients showed a carcinomatous deposit in the bladder-wall, which had not been observed even after the most careful examination. If a tumor be limited to the posterior wall of the bladder, by placing the patient on the back, and completely emptying the bladder, one can, with one finger in the rectum and the other over the pubes, outline the position of the tumor much better than it can be done with a searcher and with fluid in the bladder.

He would like to ask the author which variety of tumor he had found most common, and in what proportion of cases does the growth involve the mucous structure of the bladder.

Dr. Ferguson said that he had found the papilloma most frequently, although it was not uncommon to find a papilloma mixed in with some other variety. He could not give the exact proportion of cases in which the muscular structure was involved, but he thought they were very few.

Malignant Adenoma of the Uterus.—Dr. Elizabeth N. Cushier presented a specimen of malignant adenoma of the uterus, which had been removed from a patient, fifty-six years of age, who had passed the menopause about eight years. The first symptoms of the disease were noticed about nine months ago, at which time there were slight hemorrhages from the uterus and some pain referred to the right side. Last fall, the symptoms becoming more severe, she was sent to the infirmary, when portions of tissue were removed with the curette, and submitted to Dr. J. S. Ely, who reported that the disease was a malignant adenoma. The uterus, when removed one or two weeks later, showed on section but slight involvement of the mucous membrane, no fungosities except in one small spot, and a small mucous polypus near this point, in addition to the adenoma, which formed a circumscribed mass about the size of a bean. It was not until a section had been removed from the uterus that the whole organ was found to be extensively diseased.

Dr. J. S. Ely said that the intention in calling this "malignant" adenoma was to distinguish it from adenomatous hyperplasia, a hyperplasia of all the elements of the mucous membrane, but not involving the deeper tissues.

Interstitial Myocarditis.—Dr. George P. Biggs presented specimens illustrating interstitial myocarditis. The specimen was from a man, sixty-two years of age, who was admitted to the New York Hospital on March 5, 1892. He gave a history of previous specific and malarial infection, and of intemperance, but the family history was negative. For three weeks he had been in bed, suffering from marked dyspnœa and marked prostration, associated with cough and bloody expectoration. On admission his pulse was 120; respiration, 40, and temperature, 97° F., and physical examination showed moist râle over both sides of the chest; cardiac sounds very feeble no murmurs. The first sound was heard most distinctly in the fifth space, six inches to the left of the median line, and the heart action was rapid but regular. There was moderate general anasarca. Examination of the urine showed it to have a specific gravity of 1.020, and to contain a trace of albumin, with hyaline casts. The expectoration continued to be bloody. He died on May 10th, and the autopsy showed general subcutaneous œdema, and fluid in all the serous cavities. The heart was about twice its normal size, and its valves were all normal. The cavity of the left ventricle was dilated the left wall was 2¼ ctm. and the anterior wall ¾ ctm. in thickness. This marked diminution in the thickness of the anterior wall was due to very extensive so called "interstitial myocarditis," which was also seen in the left half of the interventricular septum. The muscular substance had been almost entirely replaced by dense fibrous tissue, and attached to the surface were numerous firm thrombi. The marked hypertrophy of the uninvolved portion, the speaker considered to be due to the extra work thrown upon it by the very great loss of power in the affected portion. The remaining cavities of the heart were all moderately hypertrophied and dilated. In the right auricular appendix was a soft thrombus. In the left coronary artery, 2 ctm. from its origin, there was extensive calcification over an area 1½ ctm. in length. On opening the vessel, a thrombus was also found at this point, producing complete occlusion of the vessel. The specimen showed very clearly the primary degenerative character and distinctly conservative nature of the lesion known as "interstitial myocarditis." The lungs contained numerous hemorrhagic infarctions of recent formation. The other organs showed only the lesions of chronic venous congestion.

The President remarked that Sir William Gull had written an article in which he claims that plugging of the coronary artery by a thrombus produces interstitial myocarditis, while plugging of the small branches of the coronary artery, as would occur in fibrous thickenings always produces fatty changes in the heart.

Tuberculosis of the Genito-urinary Tract.—Dr. F. Tilden Brown presented a patient, and exhibited microscopical slides illustrative of tuberculosis of the genito-urinary tract. The tubercle bacilli were so numerous as to form almost a pure culture. The patient, a sailor while on shipboard, and poorly nourished, first noticed very slight hæmaturia, which disappeared after a time. About one year ago it again became troublesome, and he went to the Marine Hospital and was examined with the cystoscope, but he states that for some reason the examination was unsatisfactory. The hæmaturia was not relieved. He first came under the speaker's care about two weeks ago, and was then passing small blood-clots. Rectal examination showed slight enlargement of the lateral lobes of the prostate, and two tender nodules near the apex of the seminal vesicles. There was apparently no disease of the lungs, but the patient's voice was a little husky.

A Nematode Parasitic Worm in the Urethra.—Dr. Brown also exhibited specimens and drawings of a nematode parasitic worm taken from the urethra of a man forty-eight years of age, a native of this city, who has never lived in the tropics. Has had a urethral discharge for seventeen years. He has only had gonorrhœa once, about three years before this discharge began. Last summer the patient was referred to the speaker by Dr. Brewer and a speculum examination showed nothing except a ragged appearance of the mucous membrane of the urethra from the membranous portion to the meatus, with some œdema, and an unusual prominence of the papillæ. When this examination was made before urination white muco-purulent secretion was seen, and this was particularly abundant in the bulbar urethra. Various methods of treatment were tried during the next two months, but

vithout benefit. Treatment was then discontinued for even months. On March 27, 1892, there was a more rofuse watery, muco-purulent discharge, which he attrib- ted to an unusually violent coitus. The secretion was xamined microscopically for tubercle bacilli, but none 'as found. In one particularly thick mass, however, iere was an unstained body which resembled a nema- ode worm. Previous to this, examinations of the urine ad been negative, but albumin and blood were now ound in the urine. About eight or ten worms were found n each mounting. What he had at first supposed to be xtraneous shreds, proved after further study to be por- ons of the organism. He was not yet prepared to say here they originated.

Atrophy of One Hemisphere of the Brain.—Dr. E. D. ISHER presented a brain which had been removed from person, seventeen years of age, who had had cerebral emiplegia in childhood, probably at birth. The patient esented the usual condition—hemiplegia, marked con- actures, non-development of the bones of the upper id lower extremities, exaggerated reflexes, imbecility, id epilepsy, and the speech was limited to a few simple ords. The side of the brain opposite the paralysis of e body was very much atrophied, and the convolutions ere so much shrunken that it seemed almost as if this ortion of the brain had been subjected to the contract- g action of nitric acid; the cortex was at least one-fifth inner than that of the opposite side, and the ventricle i that side was very much dilated, and filled with fluid. he hemisphere of the cerebellum on the opposite side is also considerably atrophied, and there was degenera- on extending from the cortex through the internal cap- le and pons, down to the cord. No microscopical ex- ination had yet been made.

The chief point of interest was in regard to the cause this condition; was it the result of an injury at birth, was it due to a meningeal hemorrhage? The person is of course too old to furnish evidence of any hemor- age; there was nothing in the condition of the vessels indicate any intra-cerebral trouble, so that the condi- n must have been due to either a meningeal hemor- age, or to an encephalitis. It was another one of those ses showing the futility of any operation for the relief such a condition, unless undertaken in the second or rd year of life, and even at this time, it was extremely ely to prove fatal.

Minute Hemorrhages of the Brain.—Dr. J. S. Thacher esented a brain showing numerous minute hemorrhages the substance of the brain, the result of a blow on the id. The specimen was removed from a person who d fallen from a high scaffold. It was not uncommon find such hemorrhages after a severe blow on the head, d he thought he had seen them also in cases of appar- concussion of the brain. In one case he recalled re were first symptoms of concussion, then deepening na, and death, and only these minute hemorrhages re found.

Ruptured Tubal Pregnancy.—Dr. H. J. Boldt pre- ted a specimen of this condition, which had been re- ved from a woman who had previously given birth to eral living children. For the past four or five years had been treated for right salpingitis. She went ee weeks past her menstrual period, and was then ed with griping pain in the right ovarian region, ac- panied by a slight discharge of blood. When ex- ined by the speaker on the day before yesterday, pre- us to the operation, the uterus was found posterior, and intra-peritonal hæmatocele, instead of being retro- rine, as is usual in these cases, was ante-uterine. The ration was difficult, but the patient is doing well.

n answer to the question, "Why was not this a case of natoma?" Dr. Boldt replied, because if it were a natoma there would not be such a history, which was y characteristic of tubal pregnancy. The peculiar, k, chocolate-colored blood which was discharged n the uterus he had never seen except in connection with a tubal gestation. Besides this, the villi could be seen in the specimen.

Interstitial and Submucous Fibro-myoma of the Uterus.—Dr Boldt also presented a specimen of the above, which he had successfully removed by abdominal hysterectomy. Menstruation had been becoming more and more painful and profuse for the past eight years, so that at the time of the operation, March 6th, the flow recurred at intervals of a little over a week, and lasted for ten or twelve days. She was thirty-two years of age, had been married ten years, and had never been pregnant. The menstrual pain was unbearable, and required the free use of narcotics. She was treated for four months with galvanic currents of from fifty to one hundred milliampères, and was given internally the fluid extract of hydrastis, and although the bleeding became less profuse the pain was not relieved. At the operation, after tying off the the structures on either side, the bladder was separated, after first distending it partially with fluid to show its attachments more clearly. In this way injury during the operation is avoided. This method was suggested by Dr. Mackenrodt, the first assistant of Dr. A. Martin. Under the guidance of a finger the vagina was then pierced posteriorly from above, and sutures passed all around the cervix. The stumps of the broad ligaments were then stitched to the vagina, and the peritoneum closed over the wound. The cervix was also removed.

The speaker said that in 1889 he had first removed the entire uterus for myoma, and although at that time he had used a somewhat different method, the principle of removing the cervix also, in order to avoid the liability of sepsis, was the same. In November of the same year he had first publicly commended this method of complete removal where the condition seemed to demand a hysterectomy, but where the patient's condition rendered this operation very dangerous it should not be forgotten that supra-pubic amputation can be done more quickly and safely.

Abscess of the Liver—Death from Septicæmia.—Dr. R. W. Greene said that one year ago, last June, he was called to see a woman, forty-nine years old, who was suffering from severe colicky pains in the left side, just below the free border of the ribs. The fæces were clay-colored, but there was no jaundice. On March 17, 1891, she had another such attack, and this time there was deep jaundice within the first twenty-four hours, and clay-colored stools. After a few days, a tumor appeared beneath the surface of the liver, to the right of, and above, the umbilicus, and separated from the liver by the tympanitic resonance of the transverse colon. It increased in size, and on April 8th, an aspirating needle withdrew a very peculiar-smelling pus. On the following day, one and one half pint of this pus was evacuated, and the patient made a good recovery. She recovered quickly also from a third attack of jaundice and pain, which occurred last January, but in the latter part of February she began to have severe chills, and an irregular temperature, reaching at times to 106° F. It was then noticed that the sinus leading from the abscess had closed deeply. There were no tender spots, and no pain, and the liver was apparently not enlarged. On April 18th, she died, and a partial autopsy was permitted. The apex of the gall-bladder was found adherent to the small intestine, and at this point there was a perforation between the two; the gall-bladder was very much thickened, and contained rather thick pus. Following down the common duct and the gall-ducts, these were found to be greatly distended with the same material. Infection must have come from the communication between the gall-bladder and the intestine, the abscess being entirely confined to the gall-ducts. Two or three small pieces of stone were voided through the sinus, and a piece of stone was found at the point of perforation.

Abscess of the Lung—A Malformation of the Stomach.—Dr. J. S. Ely presented specimens which had just been removed from a man, thirty-six years of age, who

had been admitted to the Roosevelt Hospital on March 8, 1892. Three days before this, he had been suddenly seized with severe dyspnœa and orthopnœa, with some palpitation of the heart, but no cough. There was moderate cyanosis, the respirations were 20, and the pulse 130, and of high tension. There was poor pulmonary resonance, inspiration was inaudible, and expiration was prolonged. He improved rapidly under the administration of nitrite of amyl, nitro-glycerine, and iodide of potassium, and he was discharged from the hospital in about one week. He was readmitted two weeks later, on account of a return of the dyspnœa, this time accompanied by cough and rusty expectoration; pulse, 116; respirations, 48, temperature, 99° F. The physical signs were about the same as before, but the urine now contained albumin and hyaline casts. He was somewhat relieved by nitro-glycerine gr. $\frac{1}{100}$th every two hours, with chloral and potassium bromide, and on April 19th he was allowed up. The next day he went into the yard, and returned with a chill. The temperature rose to 105° F., there was cardiac palpitation and dyspnœa, and the next day there was found to be a clear serous effusion in the right pleural cavity; the patient was much prostrated and his expectoration was bloody. His temperature ranged between 101° and 104° F. until the morning of the 25th, when it fell to 98° F. He died of exhaustion on April 26th. At the autopsy, forty ounces of serum and some recent fibrin were found in the right pleural cavity. There was a spot in the middle lobe of the lung which on section proved to be an abscess of the lung, surrounded by pneumonia. There was also a rather unusual malformation of the stomach—a sort of hour-glass contraction—and as there was no thickening of the muscular walls, and hence no irregular contraction to account for this peculiar curve, it was evident that it was a distinct indentation of the lesser curvature of the stomach. The heart was very much hypertrophied, and the kidneys contracted, showing the lesion of chronic diffuse nephritis. The condition of the heart, and especially of the kidneys, would explain the dyspnœa.

The Society then went into executive session.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 26, 1892.

GEORGE HENRY FOX, M.D., PRESIDENT, IN THE CHAIR.

Nominations.—DR. FOX was renominated, but said he must, in accordance with a promise made a year ago, positively decline to run for a second term.

DR. A. S. HUNTER, ex-President and member of the Comitia Minora, wished to make a nomination and precede it with a statement. The impression seemed to have gone abroad that the Society was a sort of close corporation, managed by a committee which also controlled the election. While he did not think there was any foundation for this belief, yet inasmuch as during the past twelve years the office of President had been, with one exception, filled by a member of the Comitia Minora, he now proposed to nominate one who had never been a member of that committee. He nominated Dr. Charles Carroll Lee.

Other nominees for *President* were: Drs. Charles L. Dana and Seneca D. Powell; for *First Vice President*, Drs. C. L. Dana, William Stevens, Simon Baruch, Thomas H. Holgate; for *Second Vice-President*, Drs. William Stevens, Robert Abbe; for *Secretary*, Dr. Charles H. Avery; for *Assistant Secretary*, Dr. William E. Bullard; for *Treasurer*, Dr. John S. Warren; for *Censors*, five to be elected, Drs. G. H. Fox, L. C. Gray, A. S. Hunter, William Stevens, Samuel Lloyd, C. H. Knight, Van Valzah, R. Van Santvoord, Joseph Collins, J. W. Brannan. A large number were nominated as delegates to the State Medical Society, thirty of whom are to be elected; election to take place at the annual meeting next month.

The Operative Treatment of Tubercular Lymphadenitis.—DR. SAMUEL LLOYD read this paper. In the cases of enlargement of the glands in the neck, which had appeared at his clinic, he had looked upon the condition as one of local tuberculosis, and tried to trace the place of entrance of the tubercle bacillus. This might be in disease of the scalp, of the external auditory canal, the pharynx, etc., but the most common seat of entrance was in the mouth or nose, from decayed teeth, ulcerated gums, tonsillitis, rhinitis. Whenever the point of origin for the disease could be made out with certainty, one found the glands nearest thereto most advanced in tubercular change, and giving the impression that they had been the first attacked. These glands also often showed a larger number of tubercle bacilli than those farther away. Often, however, one's examination failed to reveal the origin of the disease. Occasionally there was a family history of tuberculosis. Often the enlarged glands followed one of the eruptive fevers, or a cold in the head or sore throat. In no case had he been able to make out a primary pulmonary invasion, in spite of the statement which had been made that the lungs or bronchial glands were usually the starting-point of the disease. A further proof that the bronchial glands were not the usual starting-point was the fact that removal of the cervical enlarged glands often ended its progress. The bacilli varied in number, according to the size and extent of involvement of the glands.

Clinically, four stages or classes might be recognized. 1. The simple inflammatory stage without degeneration but with distinct local points of infection; 2, simple glandular enlargement without recognized points of infection, and with or without a distinct tubercular history; 3 degenerated glands; 4, calcareous glands of small size—hard tubercles.

The cases in the first stage—the simple inflammatory—were the most satisfactory to deal with, for removal of the infected areas and paying attention to the constitutional condition often gave complete relief. No external applications should be made; decayed teeth, etc., should receive attention, and should relief not be prompt, extirpation of the enlarged glands should be undertaken. A careful physical examination should be made in every case. The second class of cases required essentially the same management. In cases where the glands were large but not ulcerated, absorption could sometimes be caused to take place by injections, as of carbolic acid, iodine chloride of zinc, iodoform in ether, glycerine, or in olive oil. The author had used iodoform in glycerine, ten per cent. of the former; the bottle stood in boiling water. The amount injected depended upon the age of the patient and size of the gland, varying from five minims to half a drachm; was gradually increased, and employed two or three times a week, but not always in the same gland. Strict asepsis must be observed. Rapid absorption often followed, and in one instance commencing constitutional infection manifest in the lungs promptly disappeared.

DR. W. H. PORTER was glad the fact had been recognized in this paper that tuberculosis was not an inherited disease; that no more than a predisposition to it could be inherited, while actual infection must take place before it could gain a foothold in the system. The point had also been very properly made that the bronchial glands were not a common starting-point, and this was the more important as, unlike the cervical glands, they were not within reach of the surgeon. The proper treatment was early removal of the local foci and attention to the constitutional condition.

DR. J. E. KELLY bore testimony to the efficacy of the removal of enlarged tubercular glands, and said that in cases in which it had been necessary to remove the internal jugular vein during the course of the operation, no untoward physiological result had followed.

Prophylaxis and Treatment of Cholera Asiatica.—DR. PAUL GIBIER read a brief paper with this title. H

ferred to experiments which he had made with the omma bacillus of Koch, in 1885, which had convinced m that Asiatic cholera was due to infection of the di- stive tract by this bacillus. Based on this view of the ature of the disease, treatment was recommended which id for its object removal of the toxic matter already rmed, and prevention of multiplication of the germs. rther, it was desirable to restore to the system the fluid hich had been lost in the dejecta. For the latter pur- se he preferred intestinal irrigation, with a solution of loride of sodium of the temperature of the blood, to bcutaneous injections. These injections also had a eansing effect on the bowel. One might add a non- xicant antiseptic, such as boracic acid or peroxide of drogen. A cathartic of oil or sulphates should be given uring the premonitory diarrhœa, to be followed by some sinfectant, preferably, from his view, bichloride of ercury. Sulphuric acid lemonade was destructive of e cholera germ.

Remarks on the Prevention and Treatment of Chol- a.—Dr. E. O. Shakspeare, of Philadelphia, made some marks upon the paper, based largely upon an official re- rt prepared by him in 1886. During those investiga- ons, which included an inquiry into the value of Ferrán's eventive inoculation method, he had reached the con- usion that immunity from cholera could be induced in inea-pigs at least, and those and more recent experi- ents by German and other biologists led him to believe at in time an efficient and safe way would be discovered r rendering the human subject immune. Further, he ought the State would come to rely upon preventive in- ulation for stopping an epidemic where other means d failed. While the disposition in Berlin at that time, d since, had been to ignore Ferrán, yet the work being ne there at present was more or less in line with that ne in Spain seven years ago. This mode of prevention uld in time prove to be the most potent means of ecking epidemics of cholera in such countries as India, ere it was impossible to enforce personal hygiene.

Speaking of quarantine, he said that in England mense sums of money had been expended for local giene, and there quarantine might seem less necessary; t in this country, with its immense area even so enor- us a sum spent honestly would fall far short of estab- hing such conditions as would prevent the spread of olera, and therefore quarantine restrictions were abso- ely necessary. They should, however, be carried out such a way as to be as little as possible a burden to ritime trade. Provision should be made for removal the ship's inhabitants the moment she arrived at the arantine station, and she should be allowed to go as on as possible to her dock to unload her cargo. The arantine officer and his agents should give especial at- tion to all cases of diarrhœa. It was impossible to tain this knowledge by half an hour's inspection of a p's passengers. Those passengers were almost the sole ans of conveyance of cholera into a port, and in the e of this country the danger lay almost exclusively h the immigrant class. Even in Bengal, where cholera s endemic, Englishmen were hardly ever affected, the hy natives being almost alone the victims. At quaran- e a very broad distinction should be made between in and steerage passengers, not because the latter were or, but because the conditions surrounding them and ir personal habits favored the spread of cholera.

Regarding the treatment of cholera, the speaker ught the methods of intestinal antisepsis and of intra- ous or subcutaneous injections of saline solutions ecially worthy of further trial. He was strongly in- ed to recommend salol, or one of its congeners, for e premonitory stage, and up to the fully developed ge.

Dr. Gibiér closed the discussion, and said that an ap- ent discrepancy in the results of experiments upon nea-pigs, made by different physicians, had depended on the distance of removal of the culture. Germs from the cholera patient, or near cultures were more fatal than remote cultures. The lesson taught by the infectious diseases should induce physicians especially to cry out against those social conditions which to-day led to a part of every community being filthy and living in most unwholesome surroundings.

The Treatment of Cholera Morbus.—Dr. Richard Van Santvoord, said that in presenting this paper he had yielded to a request of the President, while having nothing new to offer. Acute diarrhœa might be divided into two forms, connected by intermediate cases of mixed character: 1, Acute dyspetic or irritative diarrhœa, being caused by taking some indigestible substance which underwent fermentation and putrefaction; 2, the cholera group, including especially Asiatic cholera. These had also been spoken of as the toxic diarrhœas, the toxic matter being generated by microbes. In irritative forms of diarrhœa a variety of bacteria might develop and add to the symptoms.

In diarrhœa due to cholera morbus it was usual to rely upon evacuants, stimulants, aromatics, and antiseptics. Opium given before the bowel had been cleared worked injury by locking up the irritant, whereas later it was curative because, as the author thought, acting as a physiological antidote to the poisonous ptomaïnes. To effect this object it should be given in full doses for a short period. Alkalies and aromatics probably acted similarly to opium, though being less efficient they were not applicable alone in severer toxic cases. It had been supposed that aromatics were intestinal antiseptics, but it was questionable whether they reached the point at which they could thus act. As to antiseptic remedies, such as salol, hyposulphite of soda, salicylate of soda, napthalin, mercurial preparations, etc., he had been disappointed in all. Subnitrate of bismuth, which the author thought acted in part at least as an antiseptic, had been the only exception. It was useful in less severe cases where opium was not indicated, and in others after this remedy had done its work. He also advised washing out the lower bowel. In infants the absolute withdrawal of milk might be indicated. Good stomach digestion should be secured by pepsin, etc. The author thought physicians were guilty often of not following up their cases of diarrhœa, especially in children, leaving them to the care of the mother after the worst was over, and the case becoming chronic often ended in permanent injury to the health.

Glycerine in Hepatic Colic.—Dr. Ferrard concludes a communication to the French Academy as follows: 1. Glycerine administered by the stomach is absorbed in its natural state by the lymphatics, especially by the vessels which lead from the stomach to the hilum of the liver, and to the gall-bladder; it is even found in the suprahepatic veins. 2. It is a powerful cholagogue, and an excellent remedy for hepatic colic. 3. In relatively large dose (20 to 30 grammes), glycerine brings an end to the attack. 4. In small doses (5 to 15 grammes), taken each day in a little alkaline water, it prevents new attacks. 5 Glycerine, without being a lithotriptic, is nevertheless a valuable agent in biliary lithiasis.—*Journal de Médecine, de Paris*, April, 1892.

Hæmatemesis in Cirrhosis.—Professor Ewald (*Berlin. klin. Wochens.*, No. 23, 1892) reports the case of a man of fifty, with cirrhosis of the liver and ascites, who, after aspiration of twelve quarts of fluid, had an attack of hæmatemesis without retching or preceding nausea. A second hemorrhage was followed by collapse and death. The autopsy showed varicose degeneration and dilatation of the veins of the œsophagus, with rupture in two places. The supposition was that, by removing the fluid, pressure upon the lower abdominal vessels was released, and this blood streaming through the veins of the upper part of the body, caused too great a strain upon the already distended and diseased œsophageal vessels.

AMERICAN ORTHOPEDIC ASSOCIATION.

Sixth Annual Meeting, held in New York, September 20, 21, and 22, 1892.

The President's Address.—Dr. Benjamin Lee, of Philadelphia, began his address with a tribute to the memory of the late Dr. Buckminster Brown, of Boston.

The Inflammation of Cartilage.—He then discussed that portion of the Mutter Lectures recently delivered by Dr. E. O. Shakespeare, bearing upon the subject in question. He said that the intercellular matrix of hyaline cartilage is not homogeneous, but distinctly fibrous. In the interspaces are found cartilage-cells. The cell development appears to be indigenous, cell forming within cell, and the disintegrated outer cell-walls being compressed into endothelial cell-plates which line the lymph-cavities. The lymph-spaces communicate with each other, with the lymphatics of the perichondrium, and with those of the medullary spaces in the lines of ossification.

With regard to inflammatory process in this tissue: The superficial cells lose their fat, their nuclei first divide, and then the cell itself, developing daughter cells. If this development of daughter-cells is too rapid to allow of their becoming encapsulated, they begin to feed upon the adjacent matrix, the bundles of fibres are then loosened and separated, until their free extremities may float in the synovia of the joint, and cartilage-cells with their offspring are set free in the cavity. In cases where the proliferation is excessively rapid the matrix is completely devoured and the lymph-spaces fuse together, and masses of embryonal tissue are formed by the young cells.

From these facts Dr. Lee concluded that joint disease may arise from the cartilage without bacillary infection.

Osteitis Deformans, with a Report of Two Cases.—Dr. Henry Ling Taylor, of New York, said that the disease is a chronic inflammation of advanced life, affecting the long bones, spine, cranium, and pelvis, and characterized by pain, hypertrophy, and softening, so that the bones which sustain weight become curved. The disease does not appear to be hereditary, and no connection is traceable between it and syphilis, tuberculosis, gout, or rheumatism. The onset of the disease is insidious and the progress slow. An aching in the affected bones is usually present, but may be absent. The bone gradually becomes thickened, and if a long bone, longer. At the same time it becomes softer, and if required to sustain weight it becomes bowed. As to treatment, nothing has been found to arrest or modify the disease. Two cases were reported in detail.

Lateral Dislocation at the Knee-joint Due to Tubercular Disease or Paralysis, with Especial Reference to Treatment.—Dr. T. H. Myers, of New York, found that the deformities which occurred in these two diseases differed only in degree, and therefore thought a similar origin most probable. The relaxation or destruction of the ligaments was of much more importance, in permitting the subluxations and rotation, than the destruction of bone, and the reflex muscular spasm and shortening of the fascia the factors producing the deformity. The location of the disease did not seem to influence the position of the limb. In paralysis as well as osteitis, flexion of the limb occurred before other deformities. In that position, the internal crucial ligament mainly prevented subluxation backward, and as it was inserted to the inner side of the axis of rotation of the leg, prevented inward more than outward rotation of the tibia. The spine of the tibia prevented rotation only when the ligaments held the bones firmly in apposition. Attention was then called to the obstacles preventing reduction of this deformity and its dangers. The treatment in use for this deformity was reviewed, and the general reliance on crutches deprecated. Dr. Myers recommended, on account of its simplicity, a method he had used successfully for redeeming the troublesome outward dislocation of the tibia. By adhesive straps traction was exerted on the point longitudinally in the direction of deformity, and also diametrically opposite the subluxation by a webbing strap carried behind the head of the tibia and fastened over a sprin thrown across a large window which was cut in th plaster-of-Paris splint used, to allow room for the le bones to be drawn forward and inward. A perineal crutc completed the apparatus.

Adduction Following Fracture of the Neck of th Thigh Bone.—Dr. H. Hodgen, of St. Louis, reporte the case of a woman of twenty-five years, who sustaine a fracture of the neck of the femur from a slight fall She was treated by extension and a double-inclined plane At the end of six months there was half an inch shorten ing, and she could walk with a cane. At the end of tw years the leg began to shorten and the joint to stiffen, an ultimately it became apparently four and a half inche short and the hip anchylosed. Under chloroform the de formity could be reduced and there was motion at th joint. There was no treatment, and the result is no known.

Dr. Hodgen also reported two cases of *peripheral neu ritis* in region of the scapula, in which immediate relie was obtained by the use of an immobilizing scapular brace.

The Classification of Hip-Disease.—Dr. R. W Lovett, of Boston, said that we have no pathological knowledge sufficient to enable us to assert that certain phenomena mean that the bone is affected or that certain others mean the involvement of the synovial membrane, and that on this account a classification of hip-disease based on the pathological condition present is premature, and likely to be of little practical value.

He then went on to say that hip-disease may be divided into four well-marked clinical types, each of which corresponds to a particular type of the pathological process, namely: *a*. The destructive form, where the disease is rapid, severe, and but little influenced by ordinary treatment. Extensive infiltration of the soft parts takes place, and in most instances the disease passes on to a fatal issue. *b*. The painful form, where pain is a prominent symptom and exacerbations are common. *c*. The quiet or painless form, where pain is an unimportant factor or is entirely absent. *d*. The transient or ephemeral form, where the symptoms are mild and the course of the disease is run in a few months.

Report of Three Cases of Unusual Joint-Lesion.—Dr. B. E. McKenzie, of Toronto, reported, first, a spontaneous dislocation of the hip. This was in a woman, twenty-one years of age, who had been suffering for a short time from what appeared to be rheumatism in various joints. Manipulation was made with a view to reduction of dislocation, and the joint immobilized. The result was one-quarter of an inch shortening, no pain, and apparent anchylosis.

The second case was a complete lateral dislocation of the knee in a man, fifty-five years of age, due to a blow. It was easily reduced by traction and manipulation. The reaction was slight and recovery good. The third was a separation of the femoral epiphysis at both hips, during scarlet fever, in a boy, four years old. He had several abscesses in various parts of the body, but no symptoms pointing to the hips until he again began to walk, when the peculiar waddling gait of congenital dislocation was noticed. The limbs could be drawn down and shoved up again for a distance of about an inch and a half.

Plaster-of-Paris in Orthopedics.—Dr. A. J. Steele, of St. Louis, prefers Holstein butter-cloths to crinoline for the making of plaster bandages. This is cut at the bookbinder's, or with a cobbler's knife on a cutting-board. The bandages are rubbed with plaster, and rolled by hand in preference to using any of the various machines. Warm salted water is used for wetting the bandages to hasten the hardening. A shirt, a stocking, a flannel bandage, or sheet-cotton, covers the skin before the bandage is applied. In removing splints a groove is cut with a pocket-knife, and then the finger, or a specially con-

tructed tool, is inserted between the patient and the plint, and upon this one may cut directly down. In removing old and very hard splints a double-bladed saw, haped somewhat like a Hey's saw, is used.

Mention was also made of leather jackets, and other orms of splints made over a plaster cast.

Observations on the Ultimate Deformities of Pott's isease.—Dr. Royal Whitman, of New York, said that he ultimate deformity of Pott's disease varied with the gion involved. When either extremity is involved here is less opportunity for deformity than in the intermediate portion of the spine.

In this middle dorsal region the affection is often bacute, and not recognized in its early stages. The formity is formed by the normal posterior curvature of e spine, and by the attitude of the patient. The sease is aggravated by the movements of the ribs in spiration, and by the movements of the arms.

Dr. Whitman believes that our efforts should be rected to straightening the entire spine, above and low, to limit the kyphosis to the actual extent of the sease. The lordosis must be exaggerated, the shoulders ld back, and forward reaching prevented, and the chin ld up and the head held back. To accomplish this, a odified Taylor brace is used; and a patient wearing ch a brace was presented for examination.

Lateral Curvature.—Dr. Bradford, of Boston, reported that he had within the past year tried the application of permanent plaster-of-Paris jackets in cases of here latent curvatures, exerting a correcting pressure on the plaster jacket, while still soft, from behind forward, and from before backward, by means of a screw rce, extending from a circular steel ring which is placed ound the patient's trunk. The appliance used is similar to that described by Dr. Hoffa.

In the cases mentioned by Dr. Bradford considerable ressure could be borne by the patient without more discomfort than is occasioned by the ordinary plaster jacket. A noticeable improvement in attitude and figure followed. The method was used only in cases where the rvature was markedly resistant, and in growing patients where rigidity was not complete. The jackets were pplied every two weeks. The treatment seemed applicable only to a certain stage of the affection and ould be followed as soon as possible by lighter methods treatment.

Dr. Bradford also described a light form of appliance be used to prevent faulty attitudes in flexible cases of ral curves.

Experiments Demonstrating the Etiology of the arious Deformities of Hip-joint Disease.—Dr. A. M. elps, of New York, defined the three stages of deformities in hip-joint disease, viz., flexion, abduction, and outward rotation in the first, and flexion, adduction, and inward rotation in the second. The reason for these deformities was explained by the change in the action of muscles by the change of leverage by reason of the tion of the limb. After the limb flexed beyond twenty- and forty degrees from a horizontal plane, the glutei uscles largely became inward rotators. The outward tators became abductors, with the exception of the adratus femoris and external abductor.

The first stage is produced by the voluntary effort on part of the patient to relieve the pressure of the ligament and capsule of the joint; hence abduction, outward rotation, and flexion. Spasm of muscles a voluntary effort exaggerates the deformity of the , constituting the deformity of the second stage. w, when the flexion takes place beyond thirty degrees, often with a lesser degree of flexion, the adductors, ei and tensor vaginæ femoris rotate, and the flexion ses the deformity of the third stage, viz., adduction, tion, and inward rotation. The erratic deformities are ounted for by the destruction of bone changing or deying leverage, burrowing of pus, dislocation, perfoon of the acetabulum, and locking of the head in the pelvis, possibly location of lesion, adhesions, and irritation of special nerve plates supplying the joint. The fluid hypothesis taught by Sayre is erroneous, because many cases are unattended with fluid effusion, and many cases of all the deformities seen in hip-joint disease are extra-capsular disease. Still the deformities are seen in such cases. Other causes of minor importance were also given.

Some Remarks on the Etiology of Club foot.—Dr. Samuel Ketch, of New York, discussed the following theories: 1, Pathological changes affecting the child in utero; 2, heredity; 3, mechanical forces acting on the fœtus; 4, arrested or obstructed development; 5, non-, or retarded rotation.

Of 617 cases of club-foot observed at the New York Orthopedic Dispensary, 196 were congenital. Of these, 126 were males, 70 females; 87 occurred in both feet, 57 in the right foot, 49 in the left foot, 3 not recorded; 151 presented equino-varus, 3 equino-valgus, 14 pure varus, 2 pure valgus, 4 pure equinus, 16 calcaneus, 3 showed different forms in both feet, 3 variety not recorded.

At What Age Should the First Treatment of Congenital Club-foot be Instituted?—Dr. H. Augustus Wilson, of Philadelphia, believed that to a very large extent the changes in the structures of the bones often described is due in a large measure to postponement of appropriate treatment. This may be accounted for in either of two ways. First, that observed in uncorrected cases, where the process of ossification progresses and the partially dislocated tarsal bones become permanently deformed to suit the abnormal position of the foot; and secondly, in the cases of more or less marked severity where recourse has been had to mechanical force to stretch shortened tendons. The bones in these cases, whether deformed or not, yield to the pressure exerted and thereby become deformed and ossified in their altered shape. In most instances either of these occurrences could and should have been avoided by the early recourse to operative procedures. It is not a question of saving of time but of perfect correction. The following were his conclusions:

1. Full perfect correction should be obtained during the first month.

2. Where correction is possible without recourse to rigid restraining apparatus tenotomy should be avoided.

3. Tenotomy, syndesmotomy, or cutting of the fascia, should always be resorted to in the first month when perfect correction cannot otherwise be obtained without undue force.

4. Tenotomy should never be resorted to in infancy without being followed by developmental and restraining treatment.

5. It is misapplied mechanics to force club-feet into rigid restraining shoes, and that doing so in the first three months of infancy will produce bone deformity.

6. All apparatus employed in infancy should facilitate free motion in the proper direction and encourage the development of correlation of muscular force.

7. All methods which employ undue force in correcting or restraining club-feet should be refrained from until the child has reached the age when the bones are completely ossified. The same period should be awaited before resorting to operations upon the bones.

Manual Replacement in the Treatment of Club-foot.—Dr. Ap Morgan Vance, of Louisville, made a strong plea for forcible manual correction of the deformity of club-foot, as safer and handier than the use of instruments to accomplish the same end; and pointed out that the foot of a child would withstand an extraordinary amount of injury without ill results.

The Treatment of Club-foot by Continuous Leverage.—Dr. H. L. Taylor, of New York, referred to his paper in the Medical Record, March 8, 1890, quoting therefrom. He believed that in all cases under eight years of age, and in many older ones, the deformity may

be corrected by continuous leverage within a few weeks; then a retentive apparatus is applied, and worn for from one to several years. The correction is accomplished by simple apparatus worn continuously day and night. The anterior part of the foot is first attacked, then the posterior part, and finally the tendo-achillis. This latter is sometimes cut.

A Contribution to the Anatomy of Congenital Club-Foot.—Dr. H. L. Burrell, of Boston, presented through Dr. Lovett specimens illustrating the anatomy of club-foot in a child born at seven months, and which lived three or four hours.

As compared with the normal foot, the skin over the posterior inner border was more adherent; the size of the bellies of the muscles was normal; the sheaths of the tendons were normal; the plantar fascia was not markedly contracted, but became tense when the foot was brought to a corrected position; the astragalus was small, its neck short, the axis curved with the concavity inward, the anterior articulating surface small, the tibial articulating surface divided into two instead of three facets, and that facet articulating with the fibula was covered with connective tissue instead of glistening cartilage. The plane of the superior articulating surface was oblique and faced inwards and upwards, and the depth of the bone was greater on the outer than on the inner side; the whole bone was small.

The Treatment of Resistant Club-Foot.—Dr. E. H. Bradford, of Boston, said that in the treatment of the most persistent cases of club foot the choice is between such methods as involve the least mutilation and give the best results in the speediest time. Of these three are considered:

1. Forcible correction, preceded by thorough division of ligaments and tendons.

2. Removal of the astragalus.

3. Osteotomy of the neck of the os calcis and of the astragalus, preceded by careful division of the soft parts of the inner side of the foot.

In most cases the first method gives satisfactory results, but in a small percentage of cases relapse takes place. Excision of the astragalus corrects the deformity and gives a useful foot, but one that can hardly be regarded as perfect. In a normal foot a line drawn through the middle of the sole is a straight one, but in cases of club-foot after the removal of the astragalus the median line in front of the medio-tarsal articulation forms an angle with the median line posterior to the articulation. This is apparently due to the obliquity of the anterior facet of the os calcis. In cases where such obliquity exists it is evident that perfect correction cannot be effected either by section of the soft parts on the inner side of the foot, or by excision of the astragalus. In young children where the bones are yet chiefly cartilaginous persistent maintenance of the corrected position during walking will effect a change in the shape of the bone; but in older cases, and especially in adults, this can only be effected by operative measures, namely, by the excision of a wedge-shaped piece of bone just posterior to the line of the cartilage. When the astragalus is completely displaced, so as to prevent a complete correction of the deformity or render restoration to function impossible, it should be excised; but such cases are exceedingly rare.

Means for the Prevention of Relapse in the Treatment of Club Foot.—Dr. B. E. McKenzie, of Toronto, urged the importance of the constant continuance of the corrected position by simple retention brace at night, and the use of a specially made shoe during the daytime. In the construction of the shoe two points demand attention: 1. The last upon which the shoe is made is not the ordinary straight last, but has its anterior half deflected outward, so that when the shoe is made the part which covers the anterior half of the foot is everted. At the same time the upper of the shoe is supported on the inner side, at the part covering the head of the first metatarsal bone, by a strong counter, and on the outer side at the part corresponding to the cuboid bone and the base of the fifth metatarsal. 2. The foundation of the sh is so thickened toward the outer part, and projected o ward beyond the upper as to raise the outer border of foot, and tend to roll it over toward the inner side.

The Weight of the Body in its Relation to the Pathology and Treatment of Club-Foot.—Dr. A. B. Judso of New York, urged that the weight of the patient wa very important factor in exaggerating or correcting deformity of club-foot. He is accustomed, during first year of life, and before the child begins to walk, correct, by simple means, the lateral deformity, and th by holding the foot corrected as to its antero-poster plane, to depend upon the weight of the body to corr the equinus. The braces used by Dr. Judson ha already been described in the Medical Record, and not require further mention.

Osteo-Clasia.—Dr. Nicholas Grattan, F.R.C.S., Cork, Ireland, reported upon the results of 111 cases erated upon since 1887, by means of his screw clam For knock-knee the femur was broken 48, and the le 5 times; for bow-legs the leg was broken 27 times; club-foot 20 legs were fractured and the tarsus crush 9 times. In all the cases the results were excelle The instrument used consists of two curved bars, wh can be approximated or separated as may be desir These bars are connected together by means of a stro pivot, to one end of which is attached a cross-bar to p vent the instrument from overturning when in u Through the other end of the pivot the screw works, one end of which is attached the handle; the other e is fitted into the pressure-bar, which is straight. The part through which pressure is applied to the limb s oval in shape in order to prevent its cutting the skin. A long rod is inserted into one end of the pressure-bar o prevent its rotating when the screw is turned. In fract ing a femur the pressure-bar is applied to the inner si of the limb; in bow-legs it is applied to the outer side f the leg. In knock-knee some form of extension s applied in connection with the fixation splints. In ve severe forms of club-foot the leg is fractured just abo the malleoli, and again higher up; the foot is tu rotated and everted until the sole can be placed up the ground.

Dr. Grattan then demonstrated the working of e osteoclast, fracturing the thigh in knock-knee and the g in bow-legs in several cases, patients of Dr. Gibney at the Hospital for the Ruptured and Crippled.

Contribution to the Treatment of Club-Foot.—The Se retary then read a paper with the above title, presented by Dr. Sigfred Levy, of Copenhagen (which will appear a later issue of the Medical Record).

A Report of Six Cases of Excision of the Knee-Join—Dr. J. E. Moore, of Minneapolis, uses the incisi above the patella. In all cases the patella was remov Drainage-tubes are not recommended. The bones re united by four steel wire nails. The outer dressing of plaster of-Paris extends from the toes to the body, and the dressings are not changed for one month.

Fixation Elbow-Splint.—Dr. T. H. Myers, of New York, presented a splint, and claimed for it the follow ing:

1. It allows dressings to be directly reapplied without moving the joint.

2. The clothing covers the splint almost completely

3. Owing to its body part it affords very good fixati n, especially in the short limbs of young children.

4. Any one can construct it quickly himself, and the total cost is less than one dollar.

5. It can be adapted to fit any deformity.

Officers Elected.—The following officers were elected for the ensuing year: *President*, Dr. A. J. Steele, of St. Louis; *Vice-Presidents*, Dr. Samuel Ketch, of New York, and Dr. A. J. Gillette, of St. Paul; *Secretary*, Dr. Jam Ridlon, of Chicago; *Treasurer*, Dr. A. B. Judson, of New York.

Correspondence.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

CHOLERA IN HAMBURG—HAMBURG'S WATER-SUPPLY—THE CHOLERA CASES IN BERLIN — SYSTEM OF PROPHYLAXIS — RESULTS OF CHOLERA TREATMENT IN HAMBURG — PROFESSOR CANTANI'S METHOD OF CHOLERA TREATMENT —A GOOD WORD FOR BEER-DRINKERS.

BERLIN, September 14, 1892.

WHOEVER knows of the sanitary condition in Hamburg, xpected a terrible epidemic when it first began. Not ven Professor Koch thought that Hamburg's water sup- ly would spread the disease so rapidly. We now have ie authentic number of cases and mortality. Up to Sep- mber 10th, 13,238 cases, and 5,805 deaths are reported. ugust 26th, 991 cases were reported, and 315 deaths; ugust 27th, 1,101 cases, 456 deaths; August 28th, 036 cases, 428 deaths; August 30th, 1,086 cases, 484 eaths. According to the above statistics the mortality veraged forty-four per cent. In former epidemics in erlin the mortality was between sixty to sixty-seven per ent., so that forty-four per cent. shows a relative im- rovement. A great many of the cases belonged to rangers, who did not live here, showing a decided im- rovement in favor of treatment. Hamburg's population eing 610,000, there was 1 case to every 46 inhabitants, hereas in Berlin, in 1837 and 1849, the maximum num- er was 1 in 74 inhabitants. There were in Hamburg in 105 deaths, and in Berlin 1 in 113. The question to how cholera originated in Hamburg has given rise numerous discussions. Koch stated that the large de- ots on the American quay, built for emigrants, and hose sewage empties directly into the Elbe, introducing rms into the water, and then used for drinking pur- oses, were the starting-points. A prominent physician, rector of Hamburg's sanitary affairs, Dr. Reincke, con- adicts this statement, stating that if Koch's theories e right then Hamburg's harbor has been infected before e first genuine case of cholera appeared, and the first rious cases are not as a cause but as a result of the ater pollution.

Dr. Reincke thinks that Hamburg was, before the in- oduction of cholera, like a barrel of powder—it needed it a spark to cause a serious explosion. Such sparks e in the modern transportation of passengers, impossible prevent. No doubt refugees from Hamburg, taken ck at other places, have not caused an epidemic, owing strict isolation and disinfection. Reincke thinks that e spreading of the epidemic depends on the sanitary ndition of a locality at the time of the introduction of e pestilence, depending little or not at all on the dispo- tions of time and place (Pettenkofer). The epidemic August, in Hamburg and the north of Germany, had sagreeable climatic conditions (great heat, little rain, no under-storms). Reincke admits the possibility of the reading of the epidemic to the sanitary conditions ex- ing at present, so it is possible that Hamburg's water- pply, which is poorer than Berlin, Dantzig, and Stettin, a factor.

Hamburg's water-supply dates back to the fourteenth ntury, at which time the legislature ordered an aque- ict system. In the sixteenth and seventeenth centuries rge water-wheels were added, which, however, were de- royed by fire in 1842. In 1843 the Elbe water-supply as built with steam power, supplying only a few dis- cts. Hamburg's street cleaning, fire department, and inking-supply were constructed according to plans by ndley and Mylne, of London, in 1849. The supply mes from Rothenburg, only a little above Hamburg. he water is drawn from the Elbe through a canal e thousand metres long. In large quantities of two ndred thousand cubic metres the water is filtered and en put into cemented canals and transmitted to the ma- chinery. The quantity used three years ago was, on an average, one hundred and fifteen thousand cubic metres. This number shows that, according to a population of more than five hundred thousand, a great many houses are without artificial water-supply, and depend on Elbe water or other sources.

In 1890 Hamburg's Senate recommenced an artificial method of water filtration on the Island of Billwärdär, estimating it for a supply of one hundred and eighty thousand cubic metres of water daily, or for a population of about seven hundred thousand.

In my last letter the hope expressed that Berlin would be exempt from cholera has proven itself, for we have had thus far but eight cases of cholera and seven deaths. Three of these cases were directly from Hamburg, the fourth probably, the fifth positively, in connection with Hamburg ships.

The best system of prophylaxis thus far proven is the following: The quickest possible transportation of the suspects, for the determination of a positive diagnosis, in a hospital suitable for this purpose; the fullest disinfection of everything transported; the prompt isolation, and therefore the sending to the same hospital all persons being in contact with the suspected patients; a detention of from five to eight days; the most complete disinfection of their residences and places with which the patients have been in contact. For the general hygiene the city ordered instructions for disinfection to be distributed broadcast to the public. It was proven absolutely impossible to bring a rational prophylaxis to a million of people in a short time. The laity must be taught the principles of hygiene, and therefore it is urged that hygiene should, in early youth; in other words, it should be introduced (compulsory) in the public schools.

The question of treatment and the best remedies seem to have been the common salt infusion, 1,000 to 1,500 cubic ctm. of physiological table-salt solution under the skin, in the regio infra-clavicularis or under the skin of the abdomen. Salol seems to have been useless. The same may be said of castor-oil, opium, calomel, tannin injections, camphor, and musk. Dr. Rieder (a physician in the cholera wards of the Epindorfer Hospital) made this statement on August 30th, before the Medical Society, thus:

"As we commenced the subcutaneous table salt infusions we noticed, in a few hours in many cases, a successful termination of the clinical picture, and more markedly so on using the same infusions intra-venous. The first case which was (in stadium algidum) ice-cold, cyanotic, somnolent, and pulseless, improved during the infusion, the pulse returned after four hundred cubic ctm. had been injected; the cyanosis of face and extremities, the shrunken condition of the face disappeared—as from a deep sleep the patient awoke, opened the eyes, and spoke, giving his clinical history. We then continued to use the same form of treatment. Many hundred infusions have been used last week, night and day. The median cephalic vein has been used, but when it was abnormally narrow the sephana vein of arm. If after a few hours the pulse again sank, we tried a second and a third injection."

An interesting article on the treatment of cholera, by the Italian clinician, Arnold Cantani, of Naples, appears in the *Berlin Clinical Weekly*, September 12, 1892. According to Cantani, four points are to be considered in the treatment of cholera.

1. The limitation of the growth of the bacilli in the intestines.

2. The destruction of the chemical cholera products in the intestines.

3. Rapid elimination of the absorbed poison from the blood.

4. The rendering fluid of the already thickened blood of cholera patients.

The therapeutic importance of the two first indications are to prevent the development of the disease to its deadly blood-poisoning and blood-thickening (coagulation). The

early fulfilment of these indications demands an abortive treatment of the cholera attack.

No remedy has proven so valuable in the primary stage as intestinal irrigation of tannin; tannic acid does not only kill the cholera bacilli in a short time, but it also destroys the poisonous products produced by the same. At the same time it prolongs, through its astringent properties, the absorption of cholera poison, and also, through the acidity in the intestinal canal, the development of the comma bacilli. The quantity used is: Acid. tannic., 5–20 grams; aqua (38 to 40° C.), 1.5–2 litres; tinct. opii., gtt. xx. to xxx.

The irrigations are to be used every three to four hours or oftener, according to the intensity of the case. In the second stage of cholera, *i.e.*, in stagium algidum with threatening asphyxia, where blood-poisoning has already commenced and blood coagulation threatened, the indication is to eliminate the already absorbed poison from the blood and the removal of the blood-coagulation, as the latter interferes with the heart's action and interferes with capillary circulation in smaller vessels, lessening the vitality of the nervous system by cutting off the supply of oxygen during the blood-poisoning through paralysis and heart-muscle. It is plain that the only remedy for the most serious condition of the cholera patient, *i.e.*, coagulation of blood and poisoning of same, can only be increased by the introduction of large quantities of blood into the veins and tissues.

Cantani's method consists in infusions of hot salt-water in the following manner: To a litre of distilled water, 38–40° C. we add 4.0 grammes natrium chloratum, 3.0 natrium carbonicum. Introduce this into the ilio cæcal region under the skin. In the second stage, besides the subcutaneous infusions, the hot tanno-enteroclyse must be used to prevent new cholera poison from being absorbed. In the third stage of the cholera, in the febrile reaction stage of a severe cholera attack, the therapeutic indications depend on the secondary disease of the different organs. The treatment is therefore symptomatic, besides the effort of elimination of the cholera poison. The introduction of water into the tissues allows the patient to drink plenty of fresh water, naturally; wine, champagne, and coffee, in small quantities.

As long as the stomach can absorb fluids the hypodermic klyse and the enteroklyse must be used secondarily. From the prophylactic vaccination the author anticipates very little benefit, as patients with one attack of cholera are not proof against another in the same epidemic.

A word of comfort for beer-drinkers is the result arrived at by careful investigations of Th. Weyle, in Berlin, that cholera bacilli thrive very poorly in beer. This result Weyle attributes to the acid reaction of the beer. It is, however, important during a cholera epidemic to cleanse the beer-glasses with sterilized, or boiled, or hot water. The examination of different sorts of beer was made by Weyle in his investigations.

Salophen.—Dr. Frolich, who has experimented with this new remedy for rheumatism, found it invariably efficacious so far as relieving pain within a few days was concerned, but, like other salicylic preparations, it does not prevent relapses. He prefers it, however, because it is decomposed in the intestines, and hence does not irritate the stomach; it can be given in large doses and continued a long time, and it is tasteless.

The Measles Bacillus—Drs. Canon and Pielicke (*Berlin. Klin. Wochens.*, No. 16, 1892) think they have discovered the true bacillus of measles, which was constantly present in fourteen cases examined, both in the mouth, nose, and eyes. The size of this micro organism varies greatly, the length of the largest being that of half the diameter of a red blood corpuscle. Bouillon is the only culture medium in which the investigators were able to make the bacilli grow. They are stained with an eosin-methylene blue solution.

Medical Items.

Contagious Diseases—Weekly Statement.—Report cases and deaths from contagious diseases reported to t Sanitary Bureau, Health Department, for the week en ing October 1, 1892.

	Cases.	Death
Typhus fever	0	0
Typhoid fever	57	13
Scarlet fever	39	8
Cerebro-spinal meningitis	4	3
Measles	30	7
Diphtheria	60	19
Small-pox	7	0
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Diaphtherin, a new bactericide, is said to be powe in weak solutions and non-poisonous. It has its espec use in ulcers, burns, and in operations, but is not su able for instruments.

Facial Neuralgia, according to Professor Liebreich, relieved by the following:

℞. Butyl-chloral..... gr. xl. to lxxv.
Alcohol. rect..... f℥ ijss.
Glycerini..... f℥ v.
Aquæ dest.....q. s. ad f℥ iv.
M. Sig.: From two to four teaspoonfuls, p.r.n.

Treatment of Cholera.—The following formulæ, a cording to *Le Progrès Médical*, have been reco mended by a commission appointed to investigate t cholera in Paris: 1. Stimulating drinks are to be giv —tea, coffee, brandy, rum; the body is to be warm covered and hot-water bottles or hot bricks applied the feet. 2. For the diarrhœa, a teaspoonful of the f lowing every fifteen minutes:

℞. Acid lactic..... gm. 10.
Syr. limonis..... gm. 2.
Syr. simp..... gm. 90.
M. and pour into a quart of water.

3. For the vomiting, as well as for diarrhœa, twenty-fi drops of the following as often as either threatens:

℞. Spt. æth. comp.,
Ext. valerian ether.....āā gm. 5.
Tinct. opii..... gm. 1.
Essence menth. pip..... decigm. 0.3.

Pieces of cracked ice may also be swallowed or aërat drinks given.

Castration cannot be expected to give permanent r lief in cases of general neurosis, Brodwitz thinks, becau the ovaries simply share in the central trouble, and t original irritation may be simply increased by the adh sions and thickenings which follow operation. Furth more, melancholy, forgetfulness, and often much more s rious psychic disturbances follow, while the usual sequel molimina, heart irregularities, vertigo, etc., not to speak the loss or diminution of sexual feeling, make the oper tion one to be performed only when absolutely nec sary. Schauta recommends spaying in osteomalac when, after labor, the disease does not improve und the usual methods of treatment, and Mattersdorf recor eleven instances in his "Inaugural Thesis," Breslau, 189 where it was done in atresia of the genitals, with satisfa tory results.

Diphtheria from Rags after Nine Years.—Dr. Rhe has traced six cases of diphtheria to a sack of old ra taken from a house in which malignant diphtheria ha prevailed nine years before, and in which they had r mained undisturbed in the interval.

ON THE ORIGIN OF TYPE IN DISEASE.[1]

By EDWARD BENNET BRONSON, M.D.,

NEW YORK.

ENTLEMEN: I have the honor of welcoming you to this xteenth Annual Meeting. Of the pride that one feels ose office it is to preside over the deliberations of this sociation, the pioneer of its kind among the nations d the peer of the worthiest of its successors, you need assurance. The honorable history and achievements the American Dermatological Association in the past e promise of a future still more brilliant, with achieve-nts ever and ever greater.

Dermatology, that is, the study of affections of the taneous surface as distinct from those known as inter-l diseases, boasts of a high antiquity. The striking ap-arance of the skin affections, together with the readiness h which they were observed naturally, made them ob-ts of special interest and of particular study. But, e the study of the stars in early times, it was at first le more than an enumeration of phenomena. The malies were seen and recorded, but in what they con-ted, how and whence they arose, were questions that eived only vague and fantastical answers. The his-y of dermatology furnishes an epitome of the progress medical science through the ages. We have emerged m much of the mysticism of the past, but our gaze is yet clear, and ever new phenomena are crowding upon vision. No one can say we have not progressed, ugh neither the abundance of our literature nor the iety and intricacies of our nomenclature of themselves est this progress. They are often but the dust and oke of the conflict that we know is going on under-th. Though the accumulation of data is important, mere recording of new disease manifestations has but le significance except to the specialist. It is true our d of operation is a vast one. We see more than the dent of internal diseases, and the impulse is natural to what we see, and, what is more, make haste to give it ame. But as in astronomy it is not held the highest ievement to record the discovery of a new nebula, so industry of describing a new kind of pimple or a nge rash is but a slender contribution to medical sci-e. It is the contribution of organized knowledge that itles the specialist to honor; to offer only data and nes is to hide our talent in a napkin.

n their grouping and mutual relations the efflores-ces of a skin disease may be compared to the starry stellations; but in dermatology as in astronomy, the ervation of these visible signs is but preliminary to founder studies and calculations. When we see a eor rash across the sky, the phenomenon does not eal what the thing is except inferentially. When we blood gushing from some point on the surface of the y, our inference is that a solution of continuity has urred. The gushing blood is not the essential fact, yet the appearance of the gaping wound, except as imply a sudden and violent division of tissues nor-ly coherent and intact. I believe that every anomaly uld be capable of reduction to such like simple terms. the term anomaly implies, it is some departure from normal conditions. But what is that departure? A change has taken place. A change of what? We see the result, the accomplished fact; we may describe the lesion with all circumspection; we may give its minutest anatomy, even determine its remotest cause, and yet the question remain unanswered. The study of any phenomena, whether normal or abnormal, only reaches its legitimate conclusion when brought within the purview of scientific knowledge. The anomaly of the flashing light in the sky ceases to be an object of study the moment its meteoric character is recognized and it fits its place in known cosmic law. The study of any morbid effect in the living body is not ended till tracked to its point of departure in the normal, anatomical, and physiological facts.

Strictly speaking, an anomaly in the organism of the body is not necessarily disease, though a disease is always an anomaly. Such anomalous conditions as effect variation in species and higher development are in no sense diseases. It is only when the anomaly impairs or debases life that it can be regarded as a disease. As commonly employed the word disease always suggests the idea of a more or less complicated process. In most cases the anomaly, *per se*, is not immediately apparent. We see a collection of symptoms which are the effects, the obvious signs of a series of reactions, and this series constitutes the process. By tracing this process to its inception we arrive finally at the anomaly, the primary charge or changes that is the essence of the disease.

Every change in the actions of life, whether normal or abnormal, is the resultant of incident and inherent forces. When these forces are all so co-ordinated as to preserve the integrity of the part the result is health, the excess of force going to the promotion of growth and development. It is this ability to appropriate power from external sources that gives life its most distinctive characteristic. When this ability fails, when the inherent power of co-ordination and adaptation is unequal to the external disturbing force the result is disorder, disintegration, disease, or death.

While integration is the normal end and purpose of vital action it by no means follows that disintegration is abnormal and morbid. The one is apparently as essential a factor in life as the other. Vital action is a bipolar movement. At the anode is integration—growth; at the cathode disintegration—decay and death. One would seem to be the necessary complement of the other. The conflict of forces is never-ceasing; the old, the weak, and the unfit are continually falling by the way. There is never equilibrium, never rest. One might fancy an ultimately perfected state of life with an organism so exactly adjusted to external influences as to remain immobile and impassive under the shock of every exterior force—a crystallized living being, motionless and emotionless as a sphinx. But the only living existence of which we are cognizant is in a perpetual struggle, with inevitable defeat at the end. Its greatest gain is that temporary advantage of inherent over exterior forces that enables a unit to repair its losses or produce another unit to take up the struggle and so perpetuate it through an infinite series.

To distinguish between that disintegrating tendency that seems to be necessary, and therefore normal, and that which is abnormal and is known as disease, is not always easy. There are normal processes of involution that closely resemble certain morbid conditions. It is when

[1] An address delivered before the American Dermatological Association, at Pequot, September 13, 1892.

the involution is anomalous that it becomes disease. An alopecia that begins at an earlier period in life than that in which senile changes usually take place is anomalous, and therefore disease. The same is true of those changes in the economy which represent excessive or perverted development rather than impairment. When the exterior forces present themselves in the form of a local cutaneous irritation, as from long-continued friction, the interior forces adapt themselves to the new condition by the formation of a callus. The newly developed energy is expended in formative action. Otherwise the resultant would be disintegration with erosion, or vital derangement with inflammation or ulceration. The callus is a normal kind of auxesis that is compensatory to the excess of incident force. When a similar auxesis, as, for example, in tyloma, is the result purely of deranged interior forces, the local change is disease because anomalous. Is it not probable that in every instance of malformation and new-growth an excessive development of force presented as a local irritation is met by ill-directed or inadequate efforts at compensation? So long as the power of adjustment and adaptation is orderly and normal there is health. When the reverse of this obtains there is disease.

Anomalous action being the starting-point of all disease, how is it possible to unravel all the ensuing complications so as to reach the original anomaly. Disease is like a tangled skein, in which each strand becomes a separate element of disorder acting upon all the others and in turn being reacted upon, is torn apart and reunited, making multitudinous false connections in an infinite complexity. Through all these successive complications to trace our way to the original fault, the first twist in the tangled skein, seems an almost hopeless task. We need an Ariadne's clew to thread this maze of disease with its complex symptoms and pathological changes, a clew that leads to the primary change that is the source and origin of all the disorder.

There is a certain order and consecutiveness in the phenomena of disease that show that all is not confusion and accident. Furthermore, diseases for the most part occur in conformity with certain fixed and ever-recurring types. The typical character depends less upon the nature of the extraneous influences than upon tendencies that are inherent, upon conditions that are predetermined. The morbid unravelling of the normal processes and products of growth is in effect but a reversion of the course of normal development. Blurred and indistinct as is the image, disease is the negative picture of healthy life. Disintegration is always conditioned by the laws of integration. There is method in anarchy; there is law even in chaos.

Essentially, then, disease is not an entity. Its original motive may come from some entity without, but the cause which is most essential and which we would seek is inherent. The Minotaur of our pursuit is not the monster roaming the earth, seeking whom it may devour, but that element of disorder in the organism itself which is a necessary condition of our existence, a heritage of life. Ariadne's clew is Nature's law.

If there be a law of reversion governing disintegration and disease, then those elements of life which are at the summit, those which are the highest, and therefore the latest products of development, would naturally be the first to suffer injury. The disorder should first manifest itself in impairment of the highest function of the part concerned, then, by changes of structure, each successive change affecting structures lower and lower in the scale of development till, finally, the part either relapses into its most primitive or embryonic form or suffers total dissolution and extinction. And in general this accords with experience. There are, however, certain apparent deviations from this law that demand explanation.

In the first place, one of the earliest effects of anomalous action in the organism is often an exaltation of nervous or functional energy, either at the part affected or vicariously at some other point. It is clearly the effe of derangement in the vital forces. War is declared the economy, with accumulation of forces at one poi while there is corresponding depression at another. is a false kind of energy, an excitement that tends rapid exhaustion. In inflammation and fever, where th false energy is most pronounced, the dissipation of for and the tendency to disintegration are most rapid.

Again, apparent deviations from the law of reversion disease are met with which have their origin in certa primary conditions of development. It often happe on the one hand, that where tendencies to disintegrati or degeneration are at work those parts which are t most highly organized do not succumb first, as the sta ment of the law might lead us to expect. It is a we known fact that the more highly differentiated an orga ism or an organ is, the greater its inherent power of sistance to injurious forces or influences from witho In social organizations those regulations, customs, ar and practices of amenity that through long cultivati have become firmly established may continue long af the material prosperity has begun to deteriorate; while a community where similar products of civilization only nascent, have but just begun to develop, these are t first to become extinct, and their disappearance is t very first symptom of a relapse into savagery. So in t functional and organic life of the body we see organs complex structures so highly developed and differe ated from the surrounding parts as to acquire a certa autonomy of action, and when they become involved in morbid process their integrity may be preserved lo after the less favored tissues surrounding them have s fered serious injury. Nevertheless, even in these cas when the process of deterioration once begins in the higher structures there is reason to believe that rev sional law asserts itself and pursues its usual course, p ceeding from above downward.

This course is probably not always, perhaps rarely, a p fectly regular one. The reverse would be the case we the course of development always regular and all of s products absolutely perfect. But throughout the bo mechanism with its various systems, apparatus, orga and tissues, there is an indefinite but surely vast numb of defects and imperfections even in the best organi individuals. They constitute the *loci minoris resistent*. They are the counterpart of those highly organized e ments of the body referred to above, and which we mi term, for the sake of contrast, *loci majoris resistent*. It is the less resistant, the weaker spots of the body, th are the most vulnerable. They play a very import part in disease both at its inception and throughout s subsequent course. They are to a certain degree pe liar to the individual, though in much greater degree the race and to the species. Hence while these morb tendencies of special parts of the organism modify, and a certain extent, interfere with the regular operation f the reversional law of disease, they none the less contribute to uniformity in type, and a knowledge of th would furnish us with a most important clew.

The inherent susceptibility of the tissues is a factor disease to which I believe insufficient attention is giv Especially in this period of elevation of the paras germ as the all-important element in disease is the p played by a defective organism often overlooked. T so long as we feel sure we have established an etiologi identity between lupus and tuberculosis it seems as thou it mattered little what responsibility attaches to the herent defects of the affected part. All the blame cast on the peccant bacillus, while the lurking vice in tissue that invites it to its bed goes without not Every disease rests on a tripod of factors, to wit: Fi The primary injury, representing the incident force; s ond, the susceptibility of the part, which stands for the herent and resisting force; and third, the pathologi effect, which is the resultant. To ignore any one of the factors leaves a very unstable basis for pathological stu

and however true may be the conclusions arrived at, it stops short of the whole truth.

As stated above, susceptibilities to disease having their origin in defects or errors of development, and seldom peculiar to the individual, but occurring in greater or less degree in the same form throughout the entire human family, are largely accountable for the typical characters which most diseases assume. Taking that portion of the organism that more especially interests us, we see over and over again recurring the same morbid reactions. Thus, for example, in the mucous layer of the skin we see constantly recurring those morphological changes that produce the types of disease known as eczema, herpes, and pemphigus. The original perturbing influence may emanate from widely differing sources. It may be an effect of morbid changes at remote parts of the body, or even in the vehicles of transmission, but whatever be its source its interpretation in the skin is restricted to a limited number of reactions. The different sets of reactions of which the skin is susceptible constitute its typical diseases.

The diseases of the skin at present recognized as typical are comparatively few in number. It is not improbable that there are others remaining still unrecognized. Moreover, the recognized ones will doubtless, as time goes on, be found divisible into types more and more restricted. But aside from these there must be a vast number of reactions that are exceptional or peculiar to the individual. When strange phenomena of disease are met with there is a natural inclination to connect them with one or another of the established types, according to real or fancied resemblances. In some cases, doubtless, such phenomena represent new and atypical forms of disease. The atypical character here referred to is that which relates purely to the form of the reaction at the point affected, the morphology of the local lesion. There may be an exaggerated or unusual susceptibility to morbid action, commonly known as idiosyncrasy, but the reactions upon the affected tissue correspond ordinarily to one of the recognized morphological types. The exceptional tendency to urticaria is such an idiosyncrasy, and yet the local lesion or efflorescence is a typical form of reaction, and the particular anomaly that gives rise to it is doubtless identical with that in every case of urticaria. On the other hand, a bullous or a hemorrhagic urticaria represents a divergence from the typical form, or rather a mixture of types. The vesiculation, the hemorrhage, and the wheal, each is typical of its kind and the only difference is in the unusual combination. It is the same in an advanced case of eczema. Though the reaction in the rete is, as I believe, the essentially typical one for that disease, there become conjoined with it in the course of the morbid process other and secondary reactions, producing a complex result with polymorphous characters. But even here there is nothing irregular, not an effect that with full knowledge of the incident and resistant forces could not be predicated.

When among the composite effects of any disease no one can be singled out as essentially the lesion of the disease, the type of reaction remains obscure and the classification of the affection is difficult. Thus, in that interesting series of cutaneous phenomena described first by Mr distinguished colleague under the name dermatitis herpetiformis, the skin affections present a mixed morphological type that is difficult to characterize. The disease in its totality shows distinctly marks of a neuropathic character, and so far as the central reactions are concerned it may conform to some definite pathological type. But its expression upon the skin can scarcely be regarded as a typical dermatonosis. The only feature that appears to be constant in all attacks of the skin is the herpetiform grouping of the efflorescences. But this feature is by no means peculiar to the disease under consideration. It is an effect of a neurotic influence which I see often exhibited, not only in the herpetic diseases strictly so called, but in the exanthems of syphilis, in pemphigus, in lichen, and even in universal eczema. But whereas in each of these diseases we have effects produced in the skin that are fixed and constant, one typical for each one, in dermatitis herpetiformis the cutaneous reactions are for the most part vague and undefined, as it were a nebula of disease that has not yet settled into any regular type or form of morphological change.

The susceptibility to disease is never constant. It is ever shifting with the stage of development or with the age of the individual. The weak points differ at different periods of life, and probably at different periods in the history of the race. It is probable that certain diseases or disease-manifestations that are recognized to-day did not exist in former ages, and conversely, many of those that existed formerly are unknown now, and that not only because of variation in the causes of disease, however important a factor that may be, but largely because the susceptibilities vary at different grades and phases of development. Though the primary cause remains the same, syphilis is a very different disease in the infant from what it is in the adult. It is probably not the same disease now that it was in the fifteenth century. In the young child those features of the disease that are recognized as typical in the adult are obscured by a multitude of incidental reactions which undoubtedly reflect the imperfections and greater susceptibilities of the undeveloped infant organism. In how far a similar explanation would apply to the peculiar manifestations of syphilis described by early writers, it is difficult to say, but it is at least as fair a one as that which would ascribe them to ignorance of the disease or to lack of careful observations.

But notwithstanding there is this tendency to variation in the susceptibilities of the skin to disease, its reactions, conditioned as they are by the laws of tissue evolution and involution, preserve a certain uniformity of type throughout the ages of man and throughout the generations. It is not only that uniformity which the different constitutional diseases exhibit in the sequence of their morbid phenomena, where a central disturbance transmits disorder to many separate divisions of the organism, but that which applies to the anomalous changes or lesions to which these separate divisions are severally subject, and more especially such special and more or less independent divisions as the skin or certain of its component parts. Whatever be the source of disturbance in the skin, whether external or internal, traumatic, septic, parasitic, or neurotic, when it produces disease it does so simply as a perturbing agent, deranging the normal autonomy of the part and overwhelming the inherent power of resistance, that is, the power to convert the deranging force into normal formative action. When the deformative action that is the result has a typical character, it owes it therefore less to the source of the perturbing force from without than to the previous qualities and constitution of the affected part.

But, gentlemen, I am conscious that I have too long delayed the progress of your transactions by these abstract introductory remarks. I now take pleasure in inviting your attention to matters of livelier interest and of more practical concern.

Incompatibilities of Antipyrine.—The following drugs are chemically incompatible with antipyrine, precipitating it from an aqueous solution: 1, Carbolic acid in strong solution; 2, tannin and substances containing it; 3, tincture of iodine; 4, the chlorides of mercury. The following decompose antipyrine when rubbed up with it dry in a mortar: 1, Calomel, which forms a toxic compound with antipyrine; 2, naphthol β; 3, chloral, which with it forms an oleaginous liquid; 4, bicarbonate of sodium; when this is mixed with antipyrine, an odor of acetic ether is given off; 5, salicylate of sodium, which like chloral forms an oleaginous mixture; 6, the salts of quinine and of caffeine, the solubility of which is increased by antipyrine.—*Gazette des Hôpitaux.*

THE USE OF SMOKE AS A CURATIVE AGENT IN PULMONARY TUBERCULOSIS.

By WILLIAM C. ALBERTSON, M.D.,

BELVIDERE, N. J.

In bringing forward another agent in the treatment of pulmonary tuberculosis, I am not unmindful of the already innumerable ones that have arisen, been passed upon by the profession, and dropped completely out of sight and hearing. Nor am I heedless of the fact that the disappointment of the profession, and indeed the whole world, in the failure of Koch's tuberculin, has made further discussion wearisome in the extreme.

Still the subject is so important, the ravages of the disease so widespread and disastrous, that we should never relax our diligence in trying to discover some means for its control.

It was in the month of November, 1889, that I first began to use smoke in this disease.

That the bacillus tuberculosis is the immediate or exciting cause in phthisis seems to be well established. These germs being inhaled into a lung, that either by acquirement or hereditary predisposition has become a favorable soil, set up an inflammation. They become surrounded by an inflammatory exudate, and the tubercle is formed. By pressing on the blood-vessels, the interior of this mass is deprived of nourishment, and in the course of time it breaks down and the cavity is formed.

Now it surely stands to reason that if this be a correct picture of the disease, and that if an agent could be procured that would either destroy or inhibit the growth of the germs, or render the lung in such a condition that the germs would not grow or develop in it, then the disease could be cured. In order to accomplish this it is necessary to find an agent that is harmless to the patient as well as an efficient germicide.

One thing which to my mind largely accounts for the difficulty in doing this, and for the failure of other modes of treatment, is the fact that perhaps the most active and destructive germs are found in the centre of the tubercle, and if anything is to affect them it must penetrate the tubercle to its centre. This is the workshop where the destructive work is done; the laboratory where the deadly poison is manufactured.

This is the object we wish to attain with smoke. The penetrating quality of smoke is a very prominent and useful one. The farmer has utilized its penetrating antiseptic action in preserving his meat for summer use. The mere antiseptic action would not be enough; it must penetrate to the centre of the ham. As a matter of fact, when the meat is properly smoked the centre is reached as well as the outside. It appears to me that this property of penetrability is a most valuable one, in fact the most essential one.

However, it is not enough to demonstrate that smoke is an efficient antiseptic. It must also be harmless to the inflamed and delicate lung. This could only be determined by actual trial. We know that smoke is very irritating to the conjunctival mucous membrane; but whether the mucous membrane of the respiratory tract, that is in a measure used to the passage of dust and other more or less irritating substances over its surface, would be injured by it, was to be determined alone by trying it. After nearly two years and a half of constant trial, I might almost say indiscriminate use, I can state that I have never seen a single instance in which it has been in any way injurious to the lung or bronchial mucous membrane. It does at times irritate the throat of certain persons, but on reaching the lungs it becomes distributed over a much greater area, so that, in my estimation, it is entirely harmless in every respect. What is more, I have never met with a patient whose throat did not become accustomed to the smoke, and who could not take it with impunity after a time of judicious trial. In one case a person was put upon the smoke treatment who had always had a very delicate throat which would become sore and inflamed on very slight provocation. When she first began inhaling the smoke she lost her voice entirely. The smoke was stopped for a few days and then cautiously begun again. This time she experienced very little difficulty, and soon got so that it had no effect on her throat whatever.

Just what the antiseptic action is due to, is a question for the chemist to answer. It may be said that it is only the creasote, and that creasote could be and has been administered alone without the carbon and other substances, either useless or injurious; but I do not think the small quantity of this substance in the little amount of smoke that is used would be at all sufficient, and it appears to me that the good effect must also depend, at least to some extent, on other products of combustion. I think it probable also that the smoke could be decarbonized in some way so as to entirely exclude that element while retaining the other and essential ones. However, the necessity of the creasote has led me to use the sawdust of beech-wood alone in my experiments, as it is from this that the best creasote is procured. The smoke is obtained by the combustion of beech-wood sawdust and I have tried several methods of administration. The only practical ways are by introducing smoke in a compartment in which the patient is placed, or by smoking it in a pipe as men do tobacco. The latter was tried first. The objections to this method are that it is often hard and sometimes impossible, to teach patients, especially ladies, to inhale properly, although by determined effort on the patient's part it can usually be done. The sawdust does not burn very readily, and requires a great deal of puffing, and the effort at this and to inhale it often quite tiresome. Some harmless substance which burns easily could be mixed with the sawdust, and these objections would be partially overcome. By this method also the smoke is more dense in the throat and more apt to irritate it, especially if the sawdust be green, when the smoke becomes much more irritating. The advantages are that it is convenient, can be used at any time, and the cost is nominal, which in itself is a very great item. I usually direct that the common clay-pipe be used, as it is very cheap, and when one becomes old or strong it is thrown away and another used.

This has been the method by which almost all my cases have been treated, as in the country it is next to impossible to get the patients to come to one's office sufficiently often, and the patients also have preferred the pipe. They will often not take the trouble to provide a box or cabinet, and a closet is not always available. I have a cabinet in my office, and am now insisting on my patients coming there, as they are under the direct care of the physician himself, which is always advisable.

The length of time that the smoke should be used varies much in each case. It might be broadly stated from two to six months. Cases vary so much in the course that it is impossible to tell before trial in any individual case.

My experience has been that patients using nothing but smoke begin to see some improvement in about two or three weeks, but this is often slow and hesitating, as they feel better one day and then worse the next. This depends, to a certain extent, upon their mode of living, and the care they take of themselves.

For the first two weeks the cough is usually increased, but generally only during the time of treatment, and then it is almost always accompanied by an increased power to expectorate. The sputum is more easily raised and often more abundant. Generally at the end of this time both cough and expectoration are much diminished and continue to decrease, until in the course of time they cease entirely, or almost so. An increase of bodily weight is a noticeable symptom. This almost always takes place during the first month, and is a valuable indication, as no special tonics or nutrients are given which would naturally increase weight.

The other symptoms disappear as the case improves

The temperature soon falls, but the pulse-rate is at times the last to return to normal, as it may be the first symptom of consequences to make its appearance.

The treatment by smoke need not interfere with the ordinary one. While in my experiments I have not used any medication other than occasional remedies for a troublesome symptom, still, in ordinary cases, it would be of advantage to do so, and the smoke will not interfere in any way.

Any other antiseptic, such as the oil of eucalyptus, could also be used on the sawdust. The heat would volatilize it readily, and it may be that it would be rendered more capable of penetrating the lung tissue.

While I have never used the smoke for any other disease, it might prove valuable in others, especially diphtheria, where it would be the easiest of all remedies to administer, particularly in the case of children. This, however, is merely a suggestion, as I have had no experience in it.

Of course in the case of this agent it is necessary to use the best discretion and judgment as to whom and how much to administer. How often and how long to leave the patient in the smoke can readily be ascertained by personal care in each case, as also the density of the smoke. It may be urged that this is a very loose way of arriving at the dosage of any substance, and that it would be impossible to regulate the dose; but this is a matter of experience, and one can soon find out about what each can stand. I generally begin very cautiously, leaving the patient in the smoke but a few minutes to begin with, and gradually increase the time up to thirty or forty minutes two or three times a day.

The object of this communication is merely to bring the matter before the profession, and not to detail cases, as I wish to make more complete bacteriological researches before doing this.

I may state, however, that it has been tried in twenty-five or thirty cases, and that in all but three very marked improvement has followed, and in nearly half of them cures have taken place, or what the patients have considered cures, and have, therefore, ceased coming. The three were advanced and could not take it well.

A STUDY OF ONE HUNDRED AND THIRTY-ONE CONSECUTIVE CASES OF ENUCLEATION, IN THE PRIVATE AND HOSPITAL PRACTICE OF DR. D. B. ST. JOHN ROOSA.

By A. E. DAVIS, M.D., A.M.,

INSTRUCTOR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; ASSISTANT SURGEON IN THE MANHATTAN EYE AND EAR HOSPITAL, ETC., NEW YORK.

SINCE the valuable statistical papers of Nettleship, 1886,[1] D'Oench, 1887,[2] and Andrews, 1888,[3] no paper of great importance upon this subject has appeared. In reporting these one hundred and thirty-one cases, not only are they given in statistical form, but those which deserve special notice are reviewed.

For a better presentation of the cases we have first divided them, in a general way, into two classes—traumatic and non-traumatic; and then afterward taken them both in groups under their several diagnoses—as "enucleation for sympathetic ophthalmia," "enucleation for phthisis bulbi, etc."

Trauma, immediate or remote, occurred in sixty of the cases, or in 45.8 per cent. of all. This corresponds very nearly exactly with D'Oench's[4] report of five hundred cases; he gave forty-five per cent. as due to injury, and remarks if the history of the cases had been more complete, a number diagnosticated "phthisis bulbi," etc., would have been included in the number due to injury. And so we can say in regard to this report, for in thirty-four cases no history of injury or disease is mentioned, simply a diagnosis of "sympathetic inflammation" or "phthisis bulbi" being made. Therefore, if we limit ourselves to the cases where a cause is given, the percentage due to traumatism is much greater, being in fact, 61.8 per cent. Severe trauma, however, demanding enucleation immediately or within a few days after injury, occurred in only fourteen cases, or in about eleven per cent. of the total number. But of these fourteen we shall speak in detail later; here it is only necessary to notice that in a comparatively small number of instances is the injury so extensive as to demand an immediate enucleation; whereas the great majority of cases of traumatism are allowed to remain till they are the source of sympathetic disturbance—many times by cicatricial contraction in the fellow eye. The case of longest quietude after an injury received, in this series, was one where the injury was sustained at the age of ten, from the thrust of a penknife, which did not cause any trouble after once quieting down, which it did in a few days, until thirty-five years later, when the eye was removed on account of sympathetic irritation in the opposite eye. But injured eyes have been known to keep quiet even for a longer period than in the case just mentioned, before causing any sympathetic symptoms in the fellow eye. Four such instances are reported by Adolf Alt in his report[1] of one hundred and ten cases of sympathetic ophthalmia—forty, forty-five, fifty, and sixty years, respectively, being the periods of quietude. This question of sympathetic ophthalmia following trauma, leads us to the presentation of the first group of cases.

I. Sympathetic Ophthalmia as a Cause of Enucleation.—Of the 35 cases so diagnosticated, in 22 a cause is given for the sympathetic ophthalmia, and in 19 out of the 22 cases it was traumatism, or in 86.41 per cent. of all. Thus we see that traumatism plays even a more important part as a primary reason for final enucleation, in this special group of cases, than it did in the whole series, where it was the original cause in sixty-two per cent. of the cases. Alt, in his report of 110 cases of sympathetic ophthalmia, above referred to, after calling attention to the fact that traumatism was the cause in 83½ per cent. of the cases of sympathetic ophthalmia finally demanding enucleation, makes special notice of the 16½ per cent. attributable to idiopathic inflammations. He says: "Among those eyes which were destroyed by idiopathic inflammation, two-thirds presented ulcerations of the cornea, with incarceration of the iris, or the formation of staphyloma. Consequently, the percentage of eyes which were the cause of sympathetic troubles, without presenting cicatrices in the hard membranes, is very small (about five per cent.), and among these should be especially cited those with chalky deposits and ossifications." This shows how rare it is to have a sympathetic inflammation without a perforation of the hard membranes of the exciting eye. In fact, it has been doubted if sympathetic ophthalmia ever occurs without perforating lesion of the exciting eye. In a report[2] of 200 cases of sympathetic ophthalmia by a committee of the Ophthalmological Society of the United Kingdom in 1886 (paper read by Nettleship), all of the exciting eyes except seven, which were doubtful, gave a history of perforating lesion. And the committee thought it "extremely doubtful" if any case of sympathetic ophthalmia occurs without a perforating lesion of the exciting eye. The cases of sympathetic ophthalmia here reported certainly tend to confirm this point, for in the 22 cases where the cause is given, 19 were put down to injury, and of the remaining 3, 2 are credited to violent inflammation in the injured eye, and 1 to old granular lids and pannus. In all of these it is not only possible, but quite probable, that there was a perforation of the cornea. So much for the etiology of sympathetic inflammation which

required removal of the exciting eye. The history of the 13 cases where no cause for the sympathetic ophthalmia is recorded is very incomplete, and therefore unsatisfactory, as it is also in some of the cases where the cause is stated. Besides stating the fact that there was a sympathetic inflammation, the length of time the patient remained in the house after the operation was performed, and that the patient made a good recovery, little else is stated. Some of the remaining cases, however, are of much interest as illustrative of certain phases of this most troublesome and destructive malady—sympathetic ophthalmia.

Besides the 35 cases of sympathetic ophthalmia, there are 15 cases of sympathetic irritation mentioned in the whole series here reported.

How long an injured eye may remain quiet before causing sympathetic irritation in the fellow eye is illustrated by the following case.

Case. *Phthisis Bulbi, due to the Thrust of a Penknife Thirty-five Years previous to the Removal of the Eye, the Eye keeping Quiet all this Time.—Finally, Sympathetic Irritation.*—September 6, 1884, Robert N——, aged forty-five; lost his right eye when ten years of age, from inflammation following a wound of the eyeball by a penknife.

There is now an atrophied globe, painful at times, and tender on pressure. Cornea is opaque and has a deposit of lead in it. For past six or seven weeks his left eye has felt weak; cannot read as he did without pain, lachrymation, and photophobia. The pupil responds to light. He was first seen at the hospital, some time in July of this year. Then he could read J. No. 1 at 8 inches, w. + $\frac{1}{4}$. Present condition: R. V. = 0. Cornea opaque and globe shrunken. L. V. = $\frac{20}{30}$, J. No. 1 at 8 inches. Photophobia, lachrymation, and weakness. September 8th, right eyeball enucleated. September 15th, ordered an artificial eye. Recovered without delay or accident with a good stump.

The interval between the injury and the sympathetic trouble in this case was thirty-five years. Never can we say, because an injured eye has remained quiet for a number of years, that it will remain quiet and not cause sympathetic inflammation in the fellow eye. It is truly a hidden fire, likely to break out afresh at any day, and we are simply deluding ourselves in the security of a false hope when we act otherwise than to keep the patient under constant observation.

The following cases are of interest on account of bony choroid found to exist after the enucleation, though the real condition of the choroid was suspected before the operation, due to the stony feel of the eyes to be enucleated.

Case I. *Atrophy of Right Globe—Stony Feel to it as if Bony Choroid Existed—Has Worn a Shell over the Shrunken Globe for Twenty-one Years—Sympathetic Inflammation of the Fellow Eye.*—Mrs. W——, aged thirty-five, patient in private practice. Was first seen by Dr. Roosa, June 3, 1890. She lost the sight in the right eye from a wound from a knife. When fourteen years of age, a growth came on same eye, which was removed. Since then, twenty-one years, she has worn an artificial eye over the eyeball. Globe has been a little red, and at times has felt sore. Thinks she does not see so well with the left eye as she did, and has pain at times in it, also some photophobia. Dr. Mathewson examined her in March (present time June), gave her left eye $\frac{1}{36}$ cyl. ax. 90, and advised the removal of the right globe.

Present condition: R. V. = 0. The ball is tender on pressure; stony feel. L. V. = $\frac{20}{40}$. J. No. 1 at 7 inches, with + 1 D. C. + 2 c. ax. 90. No lesion. June 6th, right eye enucleated. Osseous formation of the choroid. Slight reaction after operation, but patient made a good recovery and was discharged on twelfth day. L. V. = $\frac{20}{40}$: $\frac{20}{30}$ w. + 50 c. ax. 105. J. No. 1 = $6\frac{1}{2}$ to 15 inches.

November 3d.—Removed a small granulation from the orbit, which had troubled her some during the summer.

December 11th.—Javal's ophthalmometer = ast. w. 1 1 D. ax. 125. L. V. = $\frac{20}{30}$ w. + 1 cyl. 125. J. No 1 w. + 50 D. C. + 1 cyl. ax. 125. Ordered both glasses

The history of the second case is incomplete. He was a hospital patient.

Case II. *Diagnosis: Atrophy of Left Globe, Sympathetic Inflammation of Right.*—Young man, aged twenty-two When a child left eye became inflamed and atrophy resulted. Three weeks ago the right eye became sympathetic The left eye was removed. Choroid degenerated into small bony mass. Plastic iritis followed in the right eye

The final result of this case is not stated.

These two cases are not only of interest in themselves but the latter adds strength to the point that, when sympathetic ophthalmia is not due to a perforating lesion of opposite eye, some chalky or osseous degeneration of the choroid in the offending eye has taken place, which, acting as a foreign body, may cause sympathetic inflammation.

Two cases of sympathetic irido-cyclitis should be reported here. And though they were not the cause of the enucleations, but perhaps the result of the operation, as in each case the irido-choroiditis attacked sound eyes which had hitherto had no symptoms whatever of any sympathetic trouble; and that, over three weeks after enucleation, the cyclitis in one case appeared twenty two days after the enucleation of a phthisical bulb, the result of a cataract extraction; and the other twenty-one days after the excision of an eye that had been injured by a flying nail. Why a destructive irido-cyclitis should appear three weeks after the above excisions in the fellow eye is hard to tell. That it was due to injury to the optic nerve of the diseased eye by the operation, as some have been led to suggest, we think an open question; for in the case of the excision of the phthisical bulb following cataract extraction, the patient made so quick a recovery as to be discharged on the third day, and in the other case the patient was discharged on the sixth day. But to report the cases.

Case I. *Diagnosis: Phthisis Bulbi following Cataract Extraction—Removal of Phthisical Globe—Patient made a Quick Recovery, but Irido-choroiditis set in in the Fellow Eye Three Weeks Later, and Destroyed it.*—June 7, 1890 Thomas M——, aged sixty-five years. The cause of phthisis in this case of cataract extraction was due to the unruly conduct of the patient, who squeezed the lids violently together the day after the operation, when the eye was being examined, and tore open the wound which had healed, from which the eye was finally lost. On June 7, 1890—two months after cataract was extracted—this atrophied globe was enucleated in the usual manner. The globe was found to be much reduced in size; not much hemorrhage. After treatment, iced cloths. June 10th, no reaction; has had no pain; stump healed. Patient discharged third day after the operation.

July 16, 1890.—Patient returned. Diagnosis: irido-cyclitis, Rt. Two weeks ago pain began to be felt in right eye; became reddened four days ago. Attended out-door clinic yesterday. Was directed to use atropine and hot water every hour. Condition: Some pain, posterior synechiæ, anterior chamber very shallow.

July 17th.—A dissection out of an amount of cicatricial tissue in the stump of the left eye was done on this date, under cocaine. The treatment for next fifteen days consisted in local treatment of right eye with hot water, atropine, leeches, and calomel internally. Eye quieted down and patient was discharged, but returned again in six weeks. While in hospital this time two iridectomies were performed, and as the T. was decidedly +, pilocarpine injections and eserine were used. Eye continued to grow worse, and on November 5th, about four months after cyclitis first appeared, the sight was only pl. On account of suicidal tendencies patient was sent home. At time of writing, 1892, the eye is soft and v = pl. (?)

The second case of irido-cyclitis was that in the eye of a boy, aged seventeen, who first came to the Manhattan Hospital on August 5, 1890, suffering from an

njury to the left eye from a flying nail, which caused a traumatic cataract. This cataract was removed, and afterward an iridectomy performed, but the eye remained painful, and was finally (November 20th) enucleated, a little over three months after injury. The patient made a good recovery and was discharged on the sixth day. Stump healed, and V. R. = $\frac{2}{20}$. No sympathetic irritation.

December 20, 1890.—Just one month after the enucleation of the left eye, the patient returned to hospital. Irido-cyclitis, Rt., was diagnosticated. Patient had noticed for a week that he could not see distinctly, and had had pain for five days. Condition: R. V. = $\frac{2}{50}$, conjunctiva red, iris discolored, and complete posterior synechiæ. Tn. —. He was put on atropine, hot water, inunctions of mercurial ointment, and at times had injections of muriate of pilocarpine. Was kept in hospital two months, and finally discharged, with V. R. = $\frac{13}{20}$.

In a few days he was again admitted to the hospital, and old treatment continued, and in addition was given some quinine. After six weeks he was again discharged, much improved. V. R. = $\frac{2}{50}$ w. — 6 D. ⌒ — 1.50, c. ad. 90. At time of writing, June, 1892, the V. has decreased until it is only $\frac{1}{200}$, and patient goes about the streets with difficulty. The plastic irido-choroiditis is slowly destroying his sight.

In the five hundred cases of reported enucleations by Œchen, there were four cases of sympathetic irido-cyclitis, all of which were lost.

In two other cases of sympathetic inflammation produced by traumatism, a poultice was used after the injury in one case, and in the other tea-leaves. How much harm the tea-leaves and poultices did is not stated, but the injurious effects of these "household remedies" are only too well known. How long these popular errors in the treatment of diseases of the eye will remain rooted in the minds of the laity remains yet to be seen. Judging from the past, however, the millennium will be close at hand ere these errors are eradicated by popular education of the masses.

It is to be noticed, also, that in the 35 cases of sympathetic ophthalmia and 12 cases of sympathetic irritation, that in no case has the sympathetic trouble been caused by a panophthalmitis, in the opposite eye. Nor in the eight cases of panophthalmitis which are reported in this paper as making occasion for enucleation, did any sympathetic symptoms occur in the opposite eye. We might be led to believe by these facts that panophthalmitis was a protective against sympathetic ophthalmia, as was commonly believed by the older ophthalmologists and is still concurred in by some, even now. So long ago as 1834, Wardrop[1] noticed that in inflammations of the eyes of horses that the fellow eye usually sympathized and was lost. unless the inflammation in the first eye was converted into a suppurative inflammation, and this was accomplished by putting lime between the lids or puncturing the eye with a nail. When this was done he noticed that the opposite eye was protected [?] and did not take on any sympathetic inflammation. Instead, however, of putting lime between the lids or puncturing the eye with a nail, he resorted to a more humane method, that of "making an incision in the cornea, and discharging through it the lens and vitreous humor." He suggested also that it "might be beneficially adopted in some diseases of the human eye." Green, of St. Louis, in a paper[2] upon the history of the operation of enucleation, 1885, rather favored this procedure of Wardrop's, as will be seen by the following comment he made upon it. "Wardrop's procedure of making a free incision of the cornea and discharging through it the lens and vitreous humor, was in effect a very complete exenteration, at least when supplemented, as it must have been, by general suppuration and destruction of the choroid; its effectiveness in affording relief from sympathetic irritation, and in protecting against the danger of sympathetic inflammation, cannot be doubted." Again, Graefe, the elder, at one time recommended and practised, for a brief period, the production of suppurative irido-choroiditis, by the use of a seton, introduced in the eyeball, as a means of guarding against sympathetic irritation and inflammation. He was probably acting upon Wardrop's views. But his proposed operation found no support in the profession, and he himself soon abandoned it.

In opposition to Green's opinion is that of Alt, in his report of one hundred and ten cases of sympathetic ophthalmia. One of his deductions from his paper bearing directly on this point is "scars in the hard membranes, whenever combined with alterations in other parts of the eye, particularly in the uveal tract, retina, or optic nerve, are capable of calling forth sympathetic affections of the other eye at any time. *Purulent panophthalmitis makes no exception.* Consequently its artificial production as a prophylactic measure against sympathetic affections is reprehensible." We agree entirely with Alt, and as 43½ per cent. of the cases that he reported were of the purulent panophthalmitic type, the conclusion to which he comes is certainly a sound one. Besides, other cases of sympathetic ophthalmia have been reported following purulent inflammations.

This brings us to a brief consideration of the modes of transmission of sympathetic inflammation, and the means of its prevention. That sympathetic ophthalmia is not transmitted from one eye to its fellow by any single route is pretty certain. This is proved by daily experience. For instance, if sympathetic inflammations extended along the optic nerve always, then resection of this nerve ought to prevent sympathetic ophthalmia. But that it does not afford such protection, even when the ciliary nerves are resected at the same time, is shown by Leber's reported case, to begin with, and others since. Not only has sympathetic inflammation followed resection of the optic nerve, but even death.

That the ciliary nerves are not the only way of transmission of sympathetic ophthalmia, is not only proved by the above case of Leber's, but is shown by the fact that where resection of the ciliary nerves alone is done, sympathetic inflammation has followed.

Snellen suggests that it might travel along the lymphatics accompanying the ciliary nerves.

Nettleship[1] thinks that it might be transmitted by the fifth nerve. His opinion for this is based on the fact that in a case of "distinctive sympathetic inflammation" which came under his care, the eyelashes of the sympathizing eye became white, while those of the exciting eye were not altered.

Alt suggests "that the entire nervous apparatus of an eye has the power of transmission; and even the sympathetic system must not be left out of view in this consideration."

Sympathetic ophthalmia may, we think, be transmitted by anyone or by all of these ways combined. The important question arises, how to prevent it? Of all methods of treatment yet devised for its prevention, the best and only efficient one is enucleation of the offending eye. All the substitutes for enucleation have so far proven failures, and of so little value that they are seldom practised. Evisceration, which at one time was proclaimed as a prophylactic against sympathetic inflammation, and was somewhat extensively practised in Germany and England, has proved of less value than enucleation, and in this country, at least, is resorted to but rarely. Optico-ciliary neurectomy is, next to enucleation, the best remedy for sympathetic affections. But none of them compare with excision, and even this fails at times to cure a sympathetic irritation or check sympathetic ophthalmia, especially if it is at all advanced. Moreover, sympathetic ophthalmia sometimes follows enucleation, though no sympathetic symptoms existed at the time of the enucleation. Two

[1] The Morbid Anatomy of the Human Eye. Second Edition, p. xlii London, 1834.
[2] American Journal of Ophthalmology, 1885, ii., p. 51.

[1] Lancet, London, 1883, ii., p. 1091.

such cases are reported in this paper, and Nettleship [1] has reported nine such cases. It is possible that a very thorough examination, made before the enucleations were performed, would have shown that sympathetic inflammation of an insidious variety then existed. At any rate, we may promise a patient that enucleation is almost, although not quite, an absolute prevention of sympathetic inflammation, if it does not exist when the operation is performed.

II. Phthisis Bulbi, as a Reason of Enucleation.—There are twenty-one cases of phthisis bulbi in this group. The history in a number of them is incomplete, but four of five of the cases deserve special notice. In six of the cases sympathetic irritation is mentioned as the immediate cause of removal of the phthisical bulb. In two of the cases poultices had been applied, and in one of these cases, the history of which is not without interest, the phthisis bulbi was the result of the use of a poultice.

Case I. *Phthisis Bulbi, Rt.—Opacity of the Cornea with Anterior Synechiæ. Lt.—Persistent Headaches not Accounted for unless due to Malaria—Insomnia.*—March 26, 1879. Josie W——, aged thirteen, some time ago had some inflammation of the right eye, and a poultice was applied for one hour. Sight of eye destroyed. Lately she had an attack of inflammation in the left eye. R. V. = 0. Ball irritable. L. V. = $\frac{20}{70}$. J. No. 4, with difficulty. Ophthalmoscope shows media clear in left, except a spot on the cornea. The right eye enucleated. The conjunctiva of the orbit had a discharge from it for two months, and more after removal of the eye. Patient was troubled with persistent headaches and wakefulness. The orbit was treated with astringents and she took quinine for headaches. She also had T +, and pain in left eye, for which two iridectomies and four paracenteses were done, and finally a cataract extraction, giving her V. $\frac{20}{20.0}$, w. + $\frac{1}{4}$ $\frac{1}{2}$.

This case certainly well illustrates the destructiveness of poultices. Another feature of the case was the intense headaches, which were never entirely relieved, though sometimes improved. No other cause than the eye trouble, unless it was malaria, could be assigned as the source of the headaches.

The most interesting case under this group, however, is that where atrophy of the globe was caused by an injury in the neighborhood of the eye, but not any injury to the eye itself. As follows :

Case III. *Atrophy of Left Eyeball due to an Injury of the Face Three-quarters of an Inch below the Eye—No Wound of the Eye or Foreign Body Found.*—October 23, 1882. Willie R——, aged nine, five weeks ago received a wound of the face three-quarters of an inch below the left eye, from the explosion of a metal cartridge, but no injury to the eye. Left eyeball atrophied now. V. = 0. No photophobia in left. R. V. = $\frac{20}{20}$. $\frac{1}{\infty}$ = $\frac{1}{\infty}$. Left eye enucleated. Patient made a good recovery.

This is the only case of atrophy of the globe following an injury in the neighborhood of the eye, but not the eye itself, that has yet been recorded. Cases of atrophy of the optic nerve may, as we all know, occur in this way ; and such cases are not rare. If any of the bones of the orbit were fractured, it could not be detected at the time of operation. No foreign body was found in the globe.

As to the original cause for the phthisis bulbi in this group of cases, in every instance but two, when a cause was given, it was traumatism ; and in the two cases not so caused it was due to violent inflammation. But whatever may be the cause of ordinary atrophied eyeballs, they deserve notice chiefly for their apparent unimportance ; for the patient and surgeon alike are prone to let such eyes remain too long not operated upon, from the mere fact of their harmless appearance, until permanent and sometimes fatal injury to the fellow eye has resulted through sympathetic inflammation.

III. Staphyloma Anterior Totalis as a Cause of Enucleation.—It is in this class of cases that contagious inflammatory disease of the eye plays so prominent a pa as the original cause of trouble. Traumatism, which ha hitherto been so important a factor as the primary caus of the necessity for removal of the eye, here takes a sec ond place. There are 17 cases, and in 11 a cause i stated for the disease. In 2 cases only was it injury ophthalmia neonatorum was the cause in 4 cases; gran ular lids in 1 ; gonorrhœal conjunctivitis in 2 ; suppura tive choroiditis in 1 ; kerato-iritis in 1. In all but 2 case the staphylomas were anterior. In the 2 cases of poste rior staphyloma, 1 was due to injury, and the other t suppurative choroiditis ; the former was accompanied b sympathetic irritation, and has the following history :

Case. *Sclero-choroidal Staphyloma Posterior—Larg Floating Bodies in the Vitreous—Posterior Synechiæ—Sightless Eye—Sympathetic Irritation in the Fellow Eye* —October 23, 1878. James L——, aged twenty-sever Three or four years ago a piece of steel flew and hit hi right eye, while drawing a hoop up so as to get it off c a keg. Pain for two or three weeks after. On takin cold and being exposed now, eye becomes irritable, an for the last two months has had pain in it, with some sym pathetic symptoms in the left eye. Reading hurts th left eye. Condition : Right eye has large floating bodie in vitreous ; posterior synechiæ. V = 0. L. V. = $\frac{20}{30}$ with bad light, dark day. Some photophobia.

October 24th, R. E. enucleated. October 29th wound healed. L. E., ciliary irritation gone. V. = $\frac{20}{20}$ $\frac{1}{\infty}$ = $\frac{1}{5}$. Patient discharged.

The other case of staphyloma due to injury happene in the case of an old gentleman who, eight years previou to the enucleation, was struck in the left eye with a piec of iron. Inflammation followed and sight was lost grad ually, after two years. Staphyloma appeared and gradu ally increased. Now has a large anterior staphyloma o cornea and sclera. Eye blind, watery, and painfu R. V. = $\frac{20}{20}$. $\frac{1}{\infty}$ = $\frac{1}{0}$. Left eye enucleated. Mad quick recovery.

The case of enucleation due to staphyloma followin kerato-iritis, was operated upon by Dr. J. B. Emerson Eight years previous to the excision the patient had bee treated for kerato-iritis in hospital, and again six month previous to the operation, but after the last attack o keratitis the eye grew gradually worse, staphyloma corne formed, and he had constant pain. Made good recover after excision of offending eye.

But little is said in the notes of the case of staphyloma depending upon suppurative choroiditis. Except that h made a quick recovery after operation, with no untoward symptoms, little else is stated.

Of the other cases of staphyloma, seven in number depending upon the contagious inflammatory diseases we shall speak of as a whole, rather than singly. It is in regard to the treatment of these cases that we wish spe cially now to speak. For the cases happening as they do, mostly in young subjects—the ophthalmia neonatorum cases, of course, in infants—the enucleation of such eye is a serious operation, mutilating the patient for life. The best treatment for these cases, indeed, is their prevention and, as they depend upon preventable causes, they should—the neonatorum cases especially—be reduced to a minimum.

However, when it comes to an operative procedure in these cases of anterior staphyloma, the question, how much to do, is an important one, and especially in chil dren.

In these cases of very young subjects, where there was a large anterior staphyloma, with lachrymation, photophobia and pain, instead of doing a complete excision at one time a Critchett major excision—that is, a partial excision—was performed. The portion of the stump thus left was al lowed to remain, and over it an artificial eye was worn after the child was old enough. But if it, at any time later, caused any sympathetic trouble in opposite eye, the remainder of the globe was removed. This procedure was followed from the fact, as Critchett has justified his oper

[1] Lancet, London, 1883, ii., p. 1091.

ation, that the orbit and side of face develop better if a portion of the globe is left than if the whole globe is removed. It is not true, however, as is sometimes supposed, that the orbit of an infant closes completely after enucleation of the eyeball. Development goes on as if the eyeball was in place, but it is seldom possible to use an artificial eye early enough to save the lids from a closing that again increases the deformity; if after the incomplete excision any sympathetic trouble should arise, the complete removal can be done afterward.

In the adults a complete removal was practised, to begin with. In no case were there any untoward symptoms following the operation.

IV. Trauma of a Severe Nature, Demanding immediate Enucleation, or within a very Short Time after the Injury occurred, in 14 Cases.—Unfortunately, the history of some of these cases which were operated upon at the hospital is not as complete as we wish them to be. In four of the cases the mere fact that the eye was injured sufficiently to demand an enucleation, and that they were traumatic cataracts, is about all that is stated. In two other cases of traumatic cataract, one was in a few days followed by purulent inflammation in the injured eye, and for that reason was excised, with a good result; the other caused sympathetic inflammation in opposite eye, and was removed, partly on that account. No final result of this case is stated. Three of the eyes were removed on account of injuries in the ciliary region, and in one of these cases sympathetic irritation was present. The first of the three cases was due to an injury from a piece of iron, causing a wound of cornea, extending into the ciliary region. Prolapse of iris with cataractous lens, field imperfect, eye soft and irritable. The second case of wound in ciliary region was produced by a blow from a spoon. The wound extended from the lower, outer one-third of the cornea into the ciliary region; sympathetic irritation. Patient made a good recovery, with disappearance of sympathetic symptoms in fellow-eye. The third case was due to an injury from a bird-shot. Eye was very painful and irritable, V. = 0.

The globe was the seat of injury in the remaining five cases. In two of the cases the rupture was partial, but called for enucleation in a few days. All three made good recoveries. Complete rupture and partial destruction occurred in the remaining three cases, two of which call for special notice. The first of these cases is remarkable for the quick subsidence of reaction, considering the gravity of the traumatism. It is as follows:

Case I. *Rupture of Left Globe from Bullet—Eye Removed on Second Day after Injury—Remarkable Quick Recovery Considering the Gravity of the Injury—Bullet still in Antrum of Superior Maxillary.*—April 27, 1891. August ——, aged forty-four. At 7.30 o'clock P.M., April 26th, the patient received a pistol-shot, the ball taking effect in the left eye, which instantly destroyed the vision of the eye. Condition: On the left upper lid are powder burns. The ball entered the eye at the middle of the lower border of the superior tarsal cartilage, passing downward and slightly outward through the cornea, lens, and vitreous, making an exit through the sclera, between the optic disk and macula, piercing the outer inferior bones of the orbit. Operation. Patient etherized, and face and appendages thoroughly washed with a solution of hot bichloride (1 to 5,000). A spring speculum was then introduced, and the eye enucleated in the ordinary way, but with more trouble than is incident to an ordinary operation. Owing to the lacerated condition of the globe it became necessary to pass a suture through it. There was considerable hemorrhage. After the eye was lifted from the socket, the course of the bullet could be felt where it had entered the bone. It led into the antrum of the superior maxillary. A V-shaped piece was removed from the upper lid, where the bullet had pierced, and edges of wound brought together with sutures. The lids were dusted with iodoform, a sponge pressed firmly over the edges of the wound, and a bandage applied, to be removed the following day, and iced cloths substituted. On the following day there was considerable reaction and some discharge, but nothing alarming. Orbit was kept clean with bichloride solution (1 to 5,000), and iced cloths applied, and at times had an opium wash. On the third day after the operation the œdema and swelling began to subside rapidly, and discharge to lessen. On the fifth day after the operation the following note was made: Patient doing exceedingly well, less œdema and less discharge. Stitches removed from lid this P.M. From this on the patient improved rapidly—the orbit kept clean with bichloride wash (1 to 5,000), lead and opium wash at times, and on sixteenth day patient was discharged.

At present writing the patient is perfectly well, the bullet never giving him any trouble. This case was operated upon by Dr. Frank N. Lewis in Dr. Roosa's absence in Europe.

The other case of severe traumatism in this connection was the result of a "Fourth-of-July" celebration.

Case II. *Rupture of Left Globe, with Lacerated Wound of Left Upper Lid—But Slight Reaction.*—July 5, 1891. Robert R——, aged twenty. On the Fourth he had the handle of a sky-rocket to hit him upon the left eye. Besides carrying away one-third of the upper lid, it tore the eyeball into shreds. Condition: Middle third of left upper lid gone; left eyeball torn into shreds; considerable reaction, but no discharge. Operation: Orbit and lids washed with bichloride solution (1 to 5,000). The remains of the eyeball removed. Edges of wound of upper lid freshened and smoothed, and brought together with sutures. Iodoform dressing.

July 6.—Dressing removed. Swelling less, and but little discharge. Open treatment of orbit afterward with bichloride solution (1 to 5,000). Wound in upper lid healed by first intention. Patient made a rapid recovery, and was discharged July 15th, nine days after operation.

This last case was operated upon by myself. The plan of open treatment with frequent washing with antiseptic solutions, practised in the last two cases, materially hastened the recovery in each, and lessened the danger to septic infection—a procedure which should be followed in all such cases, and in purulent cases without exception.

V. Panophthalmitis as a Cause of Enucleation.—There were eight cases enucleated, because of a purulent panophthalmitis. In three of the cases no cause is given for the presence of the panophthalmitis, the mere fact that it was present and that the patients made good recoveries is all that was found upon the record books. The five other cases in this group have more or less complete histories.

Case I. *Panophthalmitis Following a Blow from a Whip—Operated upon in the Active Stage of Panophthalmitis—Quick Recovery.*—Two days previous to the operation in this case, the patient was hit in the left eye with a whip. Panophthalmitis followed. Two days after injury patient came to Manhattan Eye and Ear Hospital, and the eye was removed by Dr. J. B. Emerson, in the active stage of panophthalmitis. He made a good recovery and was discharged on the eleventh day.

Case II. *Panophthalmitis Due to Rupture of the Cornea—A Foreign Body Supposed to be in the Fundus—Eye Removed in the Active Stage of Inflammation.*—William H——, aged twenty-four. Three days ago was struck on the right eye by a piece of steel, cutting the cornea all the way across. Enucleation was advised on the first day of the injury, as the eye was sightless and a piece of steel was supposed to be lodged in the fundus. Purulent panophthalmitis set in, and the eye was removed on the third day after injury. Patient made a good recovery.

Case III. *Panophthalmitis Following Traumatism of the Cornea, Iris, and Lens—Removal of the Eye in the Active Stage of Inflammation—No Untoward Symptoms in Healing.*—A piece of steel entered the anterior chamber of right eye three days ago. The piece of steel was

removed the same day with some difficulty. During the operation, however, the iris was injured also, with a loss of some of the lens matter and a little vitreous. On the following day the cornea was hazy, and the day following that the cornea became necrotic. On the third day after sustaining the injury the eye was removed. After-treatment consisted in iced cloths and cleansing. Seven days later an artificial eye was inserted.

Case IV. *Panophthalmitis Accompanied by a Growth of Thick, Yellow Œdematous Tissue, which Covered the Eyeball Completely—A Case where Poultices were Used by the Patient.*—Josie D——, aged twenty-eight. Patient was struck on left eye by a rope three years ago. Recovered from this (?). Three months ago caught cold in the eye. Poultice was applied, inflammation followed, and a growth of thick, yellow, œdematous tissue formed, which covered the eye completely, and even separated the lids. The eyeball and growth were removed. No microscopic examination. Made a good recovery.

Case V. *Panophthalmitis — Wound of Cornea and Sclera—A Foreign Body Suspected to be Lodged in the Fundus—Operation in the Active Stage of Inflammation.*—April 20, 1888. William E——, aged fifteen. Six days ago, while using a rifle, the hammer being in a bad condition, the cap exploded and was supposed to enter the right eye. Atropine has been used since the injury. Condition: R. V. = perception of light. Wound in lower part of cornea and scleral region; iris turbid and conjunctiva injected. To-day, the right eye was enucleated; a foreign body was found in the ciliary region.

All of the above cases except one were operated upon in the active stage of panophthalmitis, and in none were there any unfavorable symptoms following. In each case where a cause for the panophthalmitis was stated it was traumatic in origin. Of course, eight cases do not within themselves show a great deal, but added to the large number of the same kind already reported, they are additional evidence to the fact that enucleation does not tend to produce meningitis, even when the operation is done in the active stage of the panophthalmitis. These with the 161 cases of a like character reported by Noyes, the 12 cases of Andrews, the 38 cases of D'Oench, the 70 of Rolland, and many others without fatality, show that the operation is perfectly justifiable. Besides, in all of the reported cases of fatality after enucleations, for whatsoever cause, only one-half of them were those following the removal of eyes in the active stage of panophthalmitis. To be sure, there is a great disproportion in the number of eyes enucleated in the active stage of panophthalmitis and those removed for all other causes; nevertheless, the reports of the fatal results go to show that fatal meningitis can and does follow in other cases than those operated upon in the active stage of panophthalmitis. This throws a great doubt upon the belief that it is more dangerous to remove an eye affected with panophthalmitis than any other. If all of the cases operated upon in the active stage of panophthalmitis had been treated by the open method, that is, by not bandaging the orbit, but of leaving it open and washing it frequently with aseptic and antiseptic solutions, still fewer fatal terminations would probably have followed such operations. The after-treatment is the important feature in these cases.

We believe the position held by most American surgeons to-day is, to avoid enucleation if possible during the active stage of panophthalmitis, but if there is any urgent reason for an operation, not to hesitate in performing it.

In the case of meningitis following panophthalmitis, it has been, and is still, a question of great interest how the septic infection reaches the brain? But this we prefer to discuss under the head of meningitis rather than here.

VI. Irido-choroiditis as a Cause of Enucleation.—There are nine such cases here reported. Cases I., II., and III. have incomplete histories. All three, however, made good recoveries, as an artificial eye was ordered in each case a few days after the operation, showing that the stumps healed quickly.

Case IV. *Irido-choroiditis Terminating in Purulent Inflammation of Choroid and Vitreous—Patient's General Health Bad—This was a Case of Tedious Irido-choroiditis Following a Prolapse of Iris in Wound after Cataract Extraction.*—December 19, 1888. Mrs. E. W——, aged sixty-seven. Sight has been failing in both eyes for about one year, and the last two months has not been able to use the eyes. Rt. affected first. General health not good, has dyspepsia; no pain or redness in either eye. R. V. = perception of light; field good. L. V. = fingers at eight inches. Ophthalmoscope shows cataracts in both.

January 16, 1889, cataract in Rt. extracted in capsule. On first attempt to remove it by pressure, lens caught on iris. Then on use of capsulotome iris bled, but lens was not wounded and escaped easily without loss of vitreous. Round and black pupil; a little blood in anterior chamber. Eye cleansed and double bandage applied. Opened on second day. Iris in the wound.

January 28th —Patient convalesced slowly. February 3d, prolapsed iris cut off on account of pain. March 7th, R. V. = 0. She has had a tedious irido-choroiditis. April 3d, Eye enucleated for purulent irido-choroiditis. On opening the eye after the operation, the choroid and vitreous were found to be in a state of purulent inflammation. The patient made a quick recovery.

During the whole stage of inflammation of the right eye there was no sympathetic inflammation or even irritation in the left. The patient has since been lost sight of.

Case V. *Purulent Irido-choroiditis Following in Few Hours a Puncture of the Eyeball by a Sharp-pointed Instrument—T. +—Constant Pain—Operation Performed in the Active Stage of Inflammation.*—April 2, 1889. Mrs. S——, aged thirty-eight. Two days ago was hit upon the right eye by some object, the nature of which to her is unknown, in the hands of a cash-boy in a shop. Condition: Eyeball is injected; pupil not observed; iris discolored; no tenderness of the eyeball; feeble perception of light. Leeching and atropine. April 4th, eyeball is hard, iris is now fully distinguished; pupil blocked with cataractous material; considerable pain in the morning; very feeble perception of light; no anterior chamber. April 11th, spot near cornea on outer side of the eyeball somewhat swollen and ulcerated; no perception of light; T. +; pain. April 13th, eye enucleated. Patient made a good recovery and was discharged on May 3d.

This was a remarkable case. A purulent irido-choroiditis set in in a few hours after the injury. The œdema, which was meagre, serves to show that the eyeball was penetrated in the ciliary region by a very fine instrument, and made a wound so small that it was not certainly detected twenty-four hours later.

Case VI. *Iritis with a Questionable Choroiditis in Right Eye—False Cataract and Closed Pupil in Left Eye—Though Giving no Specific History, she Improved Rapidly under Mixed Treatment, but had a Relapse and Left Eye was Removed.*—This case is of great interest from the fact that a perfectly quiet, though sightless, eye was enucleated to see if it would not have a beneficial effect on the opposite eye, affected with irido-choroiditis which was very irritable.

December 5, 1888. Madame T——, aged thirty-three. For a month has had trouble in right eye. Left eye has a false cataract and a closed pupil. Patient seems to be in good health. No evidence of specific disease. R. V. = $\frac{20}{100}$. L. V. = 0; not sensitive. Although the patient gave no specific history, she was given $\frac{1}{2}$ grain bichloride mercury t.i.d., and potass. iodide in increasing doses, together with the local treatment of hot water and atropine in right; upon which treatment she was kept, except with occasional interruptions of the local treatment, until March 30, 1889, when the vision in the right eye had increased from $\frac{20}{200}$ to $\frac{20}{20}$ — w. + 1.25 D. The eye had quieted down, pupil was dilated, and there

was no pain or redness. Was taking 48 drops of potass. iodide t.i.d, at this time no atropine or hot water. From this time on until June 10th, the vision in Rt. failed, and was at this time only $\frac{1.8}{200}$. The potass. iodide was kept up all the time. June 10th, left eye enucleated. Patient made a quick recovery, but the vision in the fellow-eye did not increase. She was kept on mixed treatment for another six months, and vision at the end of this time was $\frac{20}{200}$. December 1, 1890, eighteen months after enucleation of the left eye, R. V. = $\frac{20}{200}$. No. 4 J. with difficulty. Eye quiet, taking nothing.

Although this patient gave no specific history, we see that the vision was increased from $\frac{20}{200}$ to $\frac{20}{50}$ on the treatment of mercury and potass. iodide; but afterward relapsed to $\frac{1.8}{200}$ under the same treatment. It was deemed best at this time to remove the opposite sightless eye, though it was quiet, and see if that would not arrest the inflammation in the eye with some vision in it. The vision was slightly increased in the right after enucleation of the left, but as mercury and potassium iodide were used for six months after the operation on the left, they may have had some effect on the increase in vision. However, eighteen months after removal of the left eye the right was still quiet, and vision in it $\frac{20}{200}$, though she had taken nothing for a year. It seems that the operation was justifiable, although the probabilities are that such an eye, when not hard or painful, would not cause sympathetic irritation. It was not removed because sympathetic irritation existed, but lest it might occur in a patient not wise enough to seek relief at an early stage.

Case VII. *Irido-choroiditis Following Traumatic Cataract—Sympathetic Irritation of Fellow eye.* — Enucleation of the injured eye resulted in a quick recovery, and in relief from all sympathetic irritation in the opposite eye.

Case VIII. *Irido choroiditis with Recurring Attacks of Pain, Traumatic in Origin—Seven Years' Duration—Piece of Steel Found in the Eye after Enucleation.*— Seven years ago was struck by a piece of steel. Has had recurring attacks of pain. Redness; T. + 1 now. Eye removed, and on cutting globe open, a piece of steel was found in the fundus. Patient made a good recovery, and had artificial eye inserted on ninth day after.

Case IX. *Specific Iritis—Frequent Attacks of Irido-choroiditis– Finally, Small Circumcorneal Staphyloma—Sympathetic Irritation of Fellow-eye— Enucleation about Seven and a Half Years after Patient was First Seen* — A gentleman, thirty-five years of age, was first seen in consultation in the latter part of 1884. He had had specific disease a few months before, which produced great impairment of the general health. Is now fairly well. V., R. E. = $\frac{20}{30}$. L. = $\frac{20}{70}$. No. 1 Jaeger fluently with each eye, the right eye is sound. In the left there are posterior synechiæ with round-like opacities of the capsule of the lens. In 1887 this left eye had gone on from bad to worse, in spite of being under excellent professional care of his physician. The vision of the left eye is reduced to $\frac{1}{50}$, the iris is bulged forward like a miniature dome, there is no anterior chamber, the vitreous is hazy; in three months vision was reduced to a quantitative perception, the right eye now has iritis in a mild form—V. = $\frac{20}{200}$. This eye recovered from this iritis, but there was occasional failure of accommodation; the vision of the right eye became $\frac{20}{50}$ in a few months, and the left eye was quiet. In 1889 he had a hemorrhage from the atrophied iris in left eye; in 1891 a hernia of the iris occurred at the upper corneal margin of the left eye; in 1892 the eye was inflamed for several weeks; when the inflammation had abated he came to Dr. Roosa. Sympathetic irritation in the fellow-eye was then present. The patient's general condition was excellent. On May 23d the eye was removed. He made an excellent recovery, sympathetic irritation entirely disappeared, and twelve days after he sailed for Europe wearing an artificial eye.

Nearly every case of irido choroiditis that calls for enucleation is traumatic in origin, and the eye is removed in most cases, not on account of the offending eye itself, but because it is producing sympathetic irritation in the fellow-eye. In the 110 cases of sympathetic inflammation reported by Alt, 30 were cases of irido-choroiditis; 23 of which were due to traumatism, recent or remote. And so here, in the 6 cases where a cause is given for the irido-choroiditis, 4 were traumatic in origin, the other 2 specific, but 1 of these was accompanied by a perforation of the cornea.

VII. Foreign Bodies in the Fundus of the Eye as a Cause of Enucleation.—Of the eyes removed on account of foreign bodies in them, three of the cases are of special interest.

Case I. *Atrophied and Irritable Eyeball Due to an Injury from a Missile Six Months Previously—A Piece of Lead Weighing Twenty-seven grains was Found in the Fundus after Enucleation, which had not been Suspected by the Attending Physician.*—February 21, 1888. Joe McD——, aged twenty-five. Six months previous to entering the hospital he was struck in the right eye by a missile from a "bean-shooter" (a forked stick with a piece of elastic attached to the forks). Not a great deal of inflammation followed, but the globe atrophied and the vision was lost. On February 21, 1888, he was admitted to the hospital and the right eye enucleated, because it was irritable. The after-treatment consisted in iced cloths applied to the orbit and cleansing. Made a good recovery and was discharged on the twelfth day. On cutting open the eye after its removal, a piece of lead, weighing twenty seven grains, was found near the bottom of the eye.

This case is remarkable for the great size of the foreign body found in the fundus, and that it should have remained so long (six months) without giving more trouble than it did. Small foreign bodies, especially if near the disk and embedded, may remain for a great length of time without giving rise to much trouble; but it is rare indeed for so large a foreign body as the one just reported to remain in an eye for more than a few days, or a few weeks at most, without creating enough disturbance in the injured eye to call for its removal. It was not supposed by the patient or his attending physician that a foreign body was in the eye. The eye was removed at the hospital because the stump was irritable.

Case II. *A Foreign Body in the Eye for Six Months without the Patient Suspecting it—In that Respect it was Similar to Preceding Case—Sympathetic Irritation in the Fellow-eye.*—February 26, 1887, Michael W——, aged forty-seven, while stripping a piece of wire from a case last August (1886), was struck in the face by the end of the wire, which flew up as it was cut off of the case with a hatchet. Did not know or suppose he had injured either eye at the time. However, the left eye soon became inflamed, and though treated, grew worse and the sight was gradually lost. Now, the accommodation of the good eye seems to be affected. February 26th, the left eye was enucleated. On cutting open the eyeball, in its centre was found the piece of wire which had done the mischief six months previously. The after-treatment consisted in iced cloths and cleansing. Artificial eye inserted on the ninth day. V., R. $\frac{20}{15}$. J. No. 1 at 8″ w. + $\frac{1}{18}$.

This patient was an intelligent man, yet he was not aware of the fact that his eye was injured at all when he was struck in the face by the wire; in fact he denied that the eye had been injured.

Case III. *Foreign Body in the Vitreous—Detachment of the Retina and Choroid.*—The patient had a piece of steel to enter the left eye four days previously to entering the hospital. Has had iced cloths and atropine, but the eye grew steadily worse and is very much inflamed now. There is an exudation in the vitreous, with detachment of the choroid and retina. The eye was removed on the fourth day after the injury. Patient made a good recovery, and was discharged on the eleventh day after.

Case IV. *Piece of Steel in the Vitreous, Followed by a Severe Inflammation and Great Pain.*—June 25, 1886, M. C——, aged forty, had an injury of left eye one month previous to entering the hospital. A severe inflammation followed, accompanied by intense pain. Extensive adhesions now. No mention was made of the condition of the other eye. The offending eye was enucleated, and the patient discharged after twelve days' stay in the hospital.

Cases V., VI., and VII. have incomplete histories. Case V. was of one day's duration. A foreign body had entered the eye, and an attempt at removal the day previous had proved futile. Upon cutting open the eyeball after removal, a piece of quarry drill, 17''' long and $\frac{1}{2}$''' wide, was found in the vitreous. In Case VI., after removal of the eye, a piece of steel, 2 mm. long, 1 mm. wide, and $\frac{1}{2}$ mm. thick, was found in the fundus; also a clot of blood in the vitreous. All that is stated in Case VII. is that the eye was removed, a foreign body found in the fundus, and that the patient made a good recovery.

Case VIII. *Foreign Body in Fundus Oculi—Traumatic Cataract—Iritis—Posterior Synechiæ—Yellowish-green Mass in the Vitreous—Sympathetic Irritation of the Fellow Eye.*—A. T——, aged fifteen. On May 25, 1892, the patient was struck in the right eye by a piece of steel from a file on which he was hammering. Vision was affected at once, but not lost entirely; there was a mist before the eye. But little pain followed the accident, and no hemorrhage. A friend thought he could see something on the eye, and tried to rub it off.

May 30th.—He was seen by the House surgeon, Manhattan Eye and Ear Hospital, at which time atropine was ordered for him.

June 7th.—The following condition was found: V. R. $= \frac{20}{40}$. V. L. $= \frac{20}{20}$. R. E. showed a scar toward nasal side of cornea; iris discolored; posterior synechiæ at the point opposite corneal scar; opacity of the lens, extending through it, also at the corresponding place; stringy opacity in the vitreous, and also a greenish-yellow mass floating about at nasal side; not much pain, although there was deep circumcorneal injection and iritis; not much tenderness on pressure; left eye normal.

June 13th.—Left eye slightly watery; some photophobia and pain on use.

June 14th.—Right eye enucleated by Dr. Roosa, assisted by Dr. Lewis. A piece of steel, surrounded by exudation-material, was found in the vitreous, one-sixth inch long, one-thirty-second inch wide; made a quick recovery, an artificial eye being inserted on the seventh day after enucleation.

The yellowish mass seen floating in the vitreous, and the streak of opacity extending through the lens into the vitreous, taken together with the sympathetic irritation in the fellow-eye, were strong indications of a foreign body being in the wounded eye, and for this reason it was removed. All sympathetic symptoms were immediately relieved, and the patient made an excellent recovery. He was not pleased, however, with the result, nor his friends; for, though intelligent people (in the common acceptance of that term), they fully expected the eye to be put back after it was removed. One of his friends, immediately after the operation, when told that the eye was out, exclaimed, "Won't you put it back?" It seems that we are expected to do anything short of raising the dead.

In regard to the toleration of foreign bodies in the fundus of the eye, a few words will not be out of place here. Of late Knapp has emphasized the point that the nearer to the disk the foreign body, the less liable is it to cause trouble. In other words, the farther the foreign body is from the ciliary region, the less liable is it to cause irritation and destruction of the eye. This point admitted, another, which is even of more importance, and which has been, we believe, generally recognized, is that a foreign body, to be tolerated by an eye, must become encapsulated and fixed. And in the reported cases of long quietude of eyes with foreign bodies in them, which have finally demanded an enucleation, the cause eventually for the operation is thought to be due to the fact that the foreign body has worked loose, causing irritation, and thus calling for interference. Again, the character of the foreign body, and condition as to cleanliness of it when it enters the eye, has to be taken into consideration. If the foreign body entering the eye is septic, it is a question but of a short time until it causes serious disturbance. On the other hand, if it be antiseptic, as is the case sometimes with powder-grains or bits of wood blown into the eye, they may remain indefinitely without causing trouble. And as two cases of very long quietude of eyes with pieces of gun-caps lodged in them—one by Webster,[1] the other by D'Oench[2]—have been reported, the question is naturally forced upon us, was not the toleration in these cases due, in part at least, to the aseptic condition of the pieces of cap, which were rendered aseptic by the explosion when blown into the eye? The case reported by Webster was of fifteen years' duration, and that by D'Oench twenty-five years.

Where the patient is so unfortunate as already to have lost one eye, and then have a foreign body lodged in the other, the only course to pursue is, if possible, to encapsulate the foreign body. This is best accomplished by keeping the patient in bed with the eyes bandaged. This has been done with the result of preserving a fairly good eye. However, any eye with a foreign body in it is liable at any time to become inflamed, and destruction of the eye ensue; and this from the fact of the foreign body working loose from its old adhesions. In his clinical lectures, Dr. Roosa, in discussing this subject, is apt to speak of the "danger line" in the eye. He says foreign bodies entering the front of the eye, passing through the cornea, are not apt to excite sympathetic irritation, unless loosened and getting into the iris or ciliary region; while those entering in that region, or just in front or behind it, laterally, whether promptly removed or not, are pretty sure, sooner or later, to produce sympathetic trouble. A suit for malpractice in a Western city brings out this point. The complaint was, that the foreign body was not removed promptly enough, and that, therefore, sympathetic inflammation ensued. In his testimony for the defence, Dr. Roosa gave as his opinion that sympathetic irritation was likely to occur in any case where the foreign body had entered, as in the one in question, in the ciliary region, no matter how skilfully and promptly the foreign body was removed. The subsequent shrinkage of the cicatrix and the consequent pressure upon the ciliary nerves, would ultimately excite this. This has not been always sufficiently kept in view. The reports of successful result from the removal of foreign bodies from the eye have often been too flattering, because the situation, of itself, would finally produce sympathetic trouble. It is better to remove the eye when the foreign body has a dangerous position than to leave it.

VIII. Glaucoma.—Seven eyes were removed as a result of this disease. Chronic glaucoma was present in three of the cases, accompanied by persistent pain in the glaucomatous eye in two instances, and by sympathetic irritation of the fellow eye in the remaining case. Secondary glaucoma with persistent pain in the glaucomatous eye, and at the same time disturbance in vision in the fellow eye, occurred in two cases. Subacute glaucoma appeared once. Absolute glaucoma in one case, with constant pain in the offending eye, completes the list. In the two cases of chronic glaucoma, and the one of absolute, where there was pain only in the glaucomatous eye, the patients were entirely relieved by the operation, and the fellow eye, so far as known, kept free from sympathetic irritation. Also in the case of chronic glaucoma with sympathetic irritation, this irritation was cured, the patient making a good recovery. Vision was o — or shadows in all of the glaucomatous eyes removed.

[1] American Journal of Ophthalmology, 1890, vii., p. 172.
[2] Archives of Ophthalmology, New York, xvi., p. 188. 1887.

In the two cases of secondary glaucoma—one following a wound and the other choroiditis—in both of which cases there was sympathetic inflammation in the opposite eye even after the enucleation, which was refused for some time after its proposal, the vision in the sympathizing eye in both instances diminished, and in one case very markedly. But to give them in detail.

Case I. *Diagnosis, Choroiditis—Opacity of the Lens—Glaucoma Secondary*—August 18, 1880, William C——, aged sixty eight. Four months ago had a severe cold, since then there has been a gradual failure of sight in the left eye. No history of injury. R. V. = $\frac{20}{30}$. J. No. 1 fluently. L. V. = shadows, cornea diffusely hazy, opacities in lens and vitreous, and choroidal charges. Eserine prescribed for left. The patient was soon relieved and was discharged, April 21, 1881. It is now about a year since patient was last seen. Last night patient had severe pain in the left eye, but not much pain now. L. V. = 0, globe hard, no reflex, hemorrhage in anterior chamber. R. V. = $\frac{20}{40}$; $\frac{20}{20}$ w.—$\frac{1}{60}$, shallow cupping of disk, media clear, good field, atrophic ring at the temporal side of the disk. Some anæsthesia of both corneas. April 23d, right eye, condition the same. Advised enucleation of the left eye, but patient refused. Eserine and hot water prescribed.

May 26, 1886 (five years since last observation).—Enucleation of left eye was done some time in 1883. Complains now of watering of the right eye. R. V. = $\frac{20}{200}$; T. +; fundus indistinct; veins full and tortuous. Advised to discontinue the wearing of artificial eye for a while and eserine for right eye.

Case II. *Diagnosis, Secondary Glaucoma Following Traumatism in Left Eye.*—November 17, 1885, W. H. Mc——, aged forty-nine. Thirteen years ago (1868), accidentally noticed that he could not see well with the left eye. Four years previous to this time (1864) he had a severe blow in the left eye with the brass of a guide-pole. It was very painful for a few days, and he was left off duty as a soldier (militia in camp) during these few days; eighteen months ago he began wearing glasses on right eye; there was a blur, but no lachrymation at the time. Present condition, R. V. = $\frac{20}{40}$; $\frac{20}{20}$ — w. + 1.75 D. J. No. 1 at 8″ with + 3.50 D. L. V. = 0; lens opaque; pupil dilated; anterior chamber shallow; globe hard. For two weeks the left eye has been sore and painful, the right eye has some ciliary congestion, lachrymation, and photophobia. Ordered cocaine and hot water for left, and advised enucleation if not relieved shortly. November 21st, left continues hard and painful. November 23d, the left eye enucleated. Patient made quick recovery. April 8, 1890, slight redness of right eye; cannot use J. 1 with his glasses; advised a + 5 D.

If we may assume to draw conclusions from so small a number of cases as the seven just reported, two points seem to be brought out by them. First, that a glaucomatous eye when sightless, constantly painful and irritable, and unyielding to the ordinary methods of treatment, should be enucleated, even though not causing sympathetic irritation; for, as shown by the two cases of chronic and the one of absolute glaucoma here reported, the patient is left without further trouble. Further, even when a sympathetic irritation is present in the opposite eye, by enucleating the offending eye it may be checked, if it has not existed too long. One of the cases of chronic glaucoma here reported is of this order—the sympathetic irritation being entirely relieved by the operation. When the offending eye is allowed to remain until a sympathetic inflammation is well advanced in the fellow-eye, or perhaps a glaucoma, an enucleation rarely checks the inflammation in opposite eye. The two cases of this kind that we have just given in detail went from bad to worse, and when last seen the sight in the remaining eye was failing gradually. The operation may do harm. We all know that it is not rare for an acute glaucoma to be started in a fellow-eye, by an operation (iridectomy) on opposite eye, for same trouble. Webster [1] has reported a case of enucleation of an eye for absolute glaucoma, where an acute glaucoma followed in the fellow-eye within thirty-six hours—the only case, he says, that had come under his observation.

[1] Trans. Amer. Oph. Soc., p. 152. Boston, 1885.

IX. Tumors as a Cause of Enucleation.—Of the four cases taken from the history books, three have incomplete histories, the one having a full history occurring in private practice. Of three cases at the hospital, one was a melano-sarcoma, one an intra-ocular tumor, and one an orbital tumor. All have been lost sight of since leaving the hospital. The case in private practice was a melano-sarcoma, the history of which is as follows:

Case I. *Tumor Within Eyeball—Melano-sarcoma Suspected—Patient very Irritable from Thinking so much about her Eyes—Insomnia.*—March 15, 1880, Mrs. R. C——, aged forty. The patient cannot see well with the left eye, it aches and is tired. The right one gets tired easily also. Does not have good appetite, but feels fairly well. Is rather pale, but well developed; does not sleep well, because she worries about her eyes. The first indication that anything was wrong with her eyes was a "scum" falling over left eye. R. V. = $\frac{20}{30}$; fundus normal. L. V. = objects; anterior chamber small; greenish reflex; T. +; intra-ocular whitish growth. March 16th, left eye enucleated. Made a quick recovery. Microscope showed the tumor to be a melano-sarcoma. It sprang from the choroid.

X. Dislocated Lens as a Cause of Enucleation.—The notes upon the three cases here reported are not complete by any means, but the cases are not without interest.

Case I. *Diagnosis, Dislocated Lens—Irido choroiditis.*—The duration of the dislocation is not stated, nor the condition of the fellow-eye. However, a note of irido-choroiditis in the offending eye is made, and this fact very likely had a deciding influence as to the removal. The patient made a quick recovery.

Case II. *Dislocated Lens—Sympathetic Irritation.*—Ten days previous to the enucleation the dislocated lens was removed in pieces, and with some difficulty. Much vitreous was lost at the time. Iritis followed. As the eye was sightless and causing sympathetic irritation in the opposite eye, and the patient desired the eye removed, enucleation was done. The sympathetic irritation was relieved; patient made a good recovery.

Case III. *Dislocated Lens—Staphyloma Cornea and Myopia.*—The lens in the right eye was dislocated two years ago, and as there is no history of traumatism, it was due, altogether likely, to the pressure behind the lens, pushing it into the deep anterior chamber caused by the staphylomatous cornea. The eye is sightless. Enucleation advised, and done. A shrivelled lens was found in anterior chamber adherent to the cornea.

Unless some urgent reason arises for the immediate removal of an eye with a dislocated lens, an attempt should first be made to extract the lens, as was done in one of the three cases just reported; but failing in this, or if the extraction does not meet the indication for which it was done, enucleation must be resorted to. The difficulty of extracting dislocated lenses is well known to all operators who have had to deal with them. It was to the end of diminishing the embarrassment in such cases that the late C. R. Agnew devised a double-pronged instrument, which he called a bident, with which he transfixed all the coats of the eyeball by puncture and counter-puncture in the ciliary region. He then left the instrument in position while the corneal section was made and lens delivered, thus preventing a further dislocation backward of the lens or escape of vitreous during the operation. Although the lens was sure to be removed by this method, and the eye in some cases preserved with more or less vision for a number of months, or perhaps years, yet the consequent inflammation produced by the bident operation, taken together with the original trouble, as a rule resulted in a sightless, and in some cases a painful, eye, which had to be removed afterward. After being practised for some years in the

Manhattan Eye and Ear Hospital, the operation with the bident has been nearly abandoned.

One operator has suggested and practised in such cases putting the patient on a table, face downward and head projecting over the head of the table, while he lay under the table and performed a flap operation and extracted the lens. He no doubt had gravitation in his favor, but we know of no other surgeon doing likewise.

Any dislocated lens which cannot be kept under constant observation should be removed, for after a time, by acting as a foreign body, it may cause iritis, iridochoroiditis, or glaucoma in the affected eye, or sympathetic inflammation in the fellow-eye. Enucleation is the ultra but certain remedy.

XI. and XII. Suppurative Keratitis and Detachment of the Retina as Causes of Enucleation.—Under the diagnosis of suppurative keratitis we find two cases that called for enucleation.

Case I. *Suppurative Keratitis Preceded by Suppurative Iritis and Cyclitis—Eyeball very much Shrunken now.*—December 4, 1888, Mary M——, aged twelve. Nine months ago had suppurative iritis followed by cyclitis and cataract in the left eye. Was seen about one month after her eye first became sore. Enucleation was advised at that time, but patient refused. The eye is simply a shrunken bulb now. V. = o. R. V. = $\frac{20}{20}$. Left eye enucleated to-day; made a good recovery. On cutting open the eyeball all the intra-ocular tissues were found degenerated.

Case II. *History—Diagnosis, Ulcer of the Cornea with Sympathetic Irritation—Left, Pannus—Phthisis bulbi, Right.*—It is questionable if this case should not have been included in those described under Phthisis bulbi. Mrs. H——, aged twenty-five. On October 2, 1876, had an inflammation (kind not stated) in right eye last April, and sight was lost. Inflammation in left eye appeared yesterday. Was awake all night from pain in left eye, which was never sore or painful until last night. Condition: Left eye, ulcer on lower and outer margin of the cornea; ciliary congestion; pain and lachrymation; V. = $\frac{20}{60}$. Right eye, pannus; phthisis bulbi; eyeball red and irritable. October 4th, ulcer of left cornea extending; eye painful; enucleation of the stump of the right eye advised. Vision of L. E. reduced to $\frac{20}{100}$. R. E. enucleated. October 7th, considerable swelling of lids of right. Left vision = $\frac{20}{15}$. October 12th, L. V. = $\frac{20}{50}$. Wound healed in right and all reaction subsided.

February 16, 1877.—After enucleation of the right eye, the ulcer of left eye healed and vision became good. An entropion operation was done with good result. A few weeks ago, an ulceration of the cornea began again without apparent cause. Patient was sent to the hospital, where she improved, then relapsed, and finally had a succession of corneal abscesses which destroyed the eye.

If the left eye in this instance had not had a recurrence of corneal abscesses without any apparent cause, and that four and one-half months after enucleation of the opposite phthisical eye, we should be disposed to think that the right phthisical bulb had something to do with the sudden attack of ulceration in the left eye in October, 1876. And though the left eye was relieved, for a while at least, by the removal of the right phthisical bulb—an indication that the right eye was the offending eye—yet the subsequent history of the case leaves this point in doubt. For, may not the first ulcer in the left have been produced by the same cause as the second one which destroyed it, and the irritation in the right phthisical eye caused by the ulcer in the left. Furthermore, no history of irritation in the right was recorded after its destruction six months previously, until the first ulcer on the left cornea appeared.

Case III. *Detachment of the Retina—Sympathetic Irritation.*—One such case only, and the simple statement that the eye with the detachment was sightless and causing sympathetic irritation, and that the patient made a good recovery after its removal, with cessation of all sympathetic symptoms in the fellow-eye, completed the history of the case.

The After-treatment.—The after-treatment has varied in the cases here reported in one important particular. In the hospital cases a bandage has not usually been applied, immediately or at all, after operation, but iced cloths have been laid upon the orbit for twenty four or thirty-six hours after the enucleation. Dr. Roosa is of the opinion that this usually is most comfortable to the patient, and that the use of a bandage does not prevent ecchymosis. But in private practice a bandage is always applied when the occurrence of hemorrhage, with no surgeon within easy call, might be a serious matter. In none of these cases has any serious bleeding occurred. It has been the practice in all cases to insert an artificial eye as early a date as possible, usually in a week to ten days. The porcelain eye acts not as a foreign body, but keeps the lids well apart, protects the stump, and is a means of healing it.

As a minor point, it should be stated that it is important that the eyelids be thoroughly opened every day after the operation, lest symblepharon occur. This has been known to happen from neglect in the after-treatment.

Casualties of the Operation.—In only a few of the cases was there an orbital cellulitis, and when this was present it was after traumatism, and was not due to the operation so much as to the original injury. The after treatment of iced cloths and frequent cleansing with antiseptic solutions in such cases resulted in a speedy resolution of the inflammation. The severest case of orbital cellulitis was that following a pistol-shot wound, and the mere fact of the patient having left the hospital on the sixteenth day after the enucleation, is an indication of the efficacy of the treatment pursued.

In no case was there a fatal result, or meningitis, which usually leads to a fatality. That there might have been had the cases, especially the traumatic and purulent ones been bandaged instead of having the open treatment, is apparent from a case reported by Priestly Smith,[1] in 1885, where he removed an eye for panophthalmitis and bandaged the orbit. A meningitis followed which came near proving fatal. He remarked upon the case as follows: "The impression left upon my mind by this case was that the patient nearly lost her life through the absorption of septic matter from the wound, and that if, instead of tightly closing the lids in the usual way, I had from the first kept the wound purified by antiseptic injections, the danger would have been much less."

The exciting cause of meningitis and the route of transmission to the brain of the infectious matter, are points that have elicited much discussion and investigation in the past, and deserve notice here. Two papers of much importance are of comparatively recent date. They embrace the number of published fatal cases of meningitis up to the date of their writing, and their conclusions thereupon. They are, first, Nettleship's,[2] 1880, and second, Andrews's,[3] 1888. Nettleship reported thirty cases of fatal meningitis, and mentioned five others that he had heard of since he had written his paper. As to the causation of meningitis, he makes this observation: "The fact of the eye having been wounded, or otherwise perforated, is of much more importance than the presence of visible pus." In support of this view he cites the fact that, in the 23 cases out of the 30, where an exciting cause is mentioned, that in 18 instances the coat of the eye had been perforated. As to the route of transmission of the infectious matter to the brain he says: "There is but little positive evidence that the inflammation extends along the sheath of the optic nerve." And again, "Owing to the free communications between the veins of the orbit, the face, the pterygo-maxillary fossa and the cavernous sinus, by a reversal of the blood-cur-

[1] Ophthalmic Review, London, 1885, iv., p. 39.
[2] Transactions of the Ophthalmological Society of the United Kingdom, 1886, vol. vi., p. 445.
[3] New York Medical Journal, 1888, vol. xlviii., p. 701.

rent in these, is a probable cause of meningitis." Another case cited by him would seem to infer that it was possible for the inflammation to extend along the fifth and sixth nerves, to wit, "In one case where there was thrombosis of the cavernous, there was pus with micro-organisms about the fifth and sixth nerves, with little or no change in the optic nerves."

That the blood, and not the optic nerve, is the channel by which the infectious matter is carried to the brain, is strongly indicated by the report (Andrews's paper just cited) "of thirteen autopsies upon fatal cases of meningitis following enucleation, in which especial attention was directed to the ascertainment by microscopic examination of the channel by which the infection was conveyed to the cranial cavity. In seven the most careful research failed to discover any evidence of inflammation of the optic nerve, and in the majority of the cases the examination as to the answering this question was negative."

But whatever may be the exciting cause of the panophthalmitis which leads to a fatal meningitis, and by whatever channel the infectious matter may be carried to the brain, we know that death after an enucleation—considering the great number of such operations—is rare; and, furthermore, that the operation is perfectly justifiable.

Artificial Eyes.—The porcelain eye, by its truly wonderful likeness to the human eye in color, size, and conformation, is a mark of the advance in ophthalmological science. If the removal of eyes in olden time was done in a rude way, as by putting lime between the eyelids, or puncturing the ball with a nail, no less primitive in its way was the artificial reproduction of the eye. The first artificial eye consisted simply of a metal shell painted or enamelled over, figuring the sclerotic and iris and leaving the cornea absent. It was not until the seventeenth century that a Dutchman made an artificial eye of enamel, and combining this with glass, succeeded in representing the cornea. However, the eyes were simple oval shells, like the half of a bird's egg, and could be worn in either orbit, there being no right or left. How different now! Not only have we rights and lefts, but the resemblance to the natural eye is so great that it often takes an expert to detect it. And how completely the public in general can be deceived by it, is illustrated by an incidental case occurring in the practice of the late Dr. Williams, of Cincinnati. A sharp-witted Irishman who had had his eye removed by the doctor, did not wish to let his neighbors know that he was wearing an artificial eye, so when he returned home he told them the old one had been taken out, scraped, and put back. Not only did he deceive his neighbors, but the county papers took it up and made so much noise that the good doctor became indignant and exposed the patient's story. Whereupon the Irishman, when next seeing the doctor, said, "Doctor, you see what a good thing I was making for you, and you went and spoiled it all."

And the belief that an eye can be taken out, scraped, and put back again, is not confined to the grossly ignorant, as shown by one case reported in this paper; hence it may be well to disabuse their minds upon this point before the operation is done.

Artificial eyes should be removed each night, washed, and kept in a dry place, and not in a glass of water, during the night, as is usually done. Two years is about the limit of time of service of an artificial eye, when it becomes rough and has to be renewed. However, Dr. Chisolmn [1] reports one case where a woman, for fear she would not be able to replace the eye if removed, wore it continuously, without once removing it, for fifteen years.

463 Fifth Avenue.

Stammering is said to be a disqualification in candidates for admission to the St. Petersburg Military Medical Academy. Think of having to pronounce "prichudlivoye sudoproizvodstvo" without stammering!

Clinical Department.

THE TREATMENT OF CARBUNCLE BY INJECTION OF CARBOLIC ACID.

By ALAN B. MURRAY, M.D.,

COKEDALE, MONT.

In the three cases thus treated, the carbuncles, situated on the posterior surface of the neck, were from two and one-half to four inches in diameter, tense, swollen, and very painful. They appeared first as mere papules, arousing no apprehension until the surrounding tissue assumed that brawny, tense appearance typical of a true carbuncle. The pain was of that pulsating variety that makes one dread each contraction of the heart. The needle of the hypodermic syringe, containing fifteen minims of pure carbolic acid, was thrust deeply into the centre of the inflamed tissue, the direction of the needle being changed three or four times while the fluid was being injected. This operation caused most intense pain for only an instant, the local anæsthetic power of the acid asserting itself almost immediately. Within forty-eight hours after this treatment the severe pain diminished, and soon became so slight that there was appreciation of inconvenience only upon exerting the action of those muscles underlying the carbuncle. The brawny and swollen tissues, before so exquisitely sensitive, became of a more healthy appearance and only slightly tender, the active inflammatory process seeming to centralize or "point."

After the tenth day the course was that of an ordinary furuncle, the carbuncle asserting itself only in the prolonged suppuration and casting off of portions of gangrenous tissue. The advantages of this method of dealing with this exceedingly troublesome affliction is, that the course of the inflammation is much shortened, the pain and general malaise to a great extent done away with, and the patient relieved of that old-time nuisance, the poultice. The relief of the pain alone would certainly be deemed, by one who has suffered with a carbuncle, sufficient excuse for this mode of treatment. The success attending this little operation would seem to warrant its more general application, not only in cases of carbuncle but in the more common furuncle. It would probably be difficult, however, in many cases, to persuade the patient to submit to this procedure on account of the attending pain. This objection may be readily overcome by spraying the carbuncle with ether until local anæsthesia has been produced; then thrusting the hypodermic needle deeply into the tissue through the anæsthetized area. No claim for originality in this treatment is made. It has been advocated at different periods for years. But the general recognition of its efficacy has not been such as one would expect from its real surgical value in such pathological conditions.

The Prognosis of Gunshot Wounds of the Chest.—The mortality following gunshot wounds of the thorax has varied greatly at different times. Thus, from a collection of statistics published by Dr. A. Claus, in the *Bulletin de la Société de Gand*, we learn that at the battle of Toulouse the mortality was eighty three to eighty-seven per cent., according to different observers; in the Crimean war the average of the statistics presented by the Russian, French, and English surgeons was eighty-nine per cent. Loeffler gives a mortality for the Prussian army, in the war with Denmark, of 68.4 per cent., and Stromeyer, for the same army in the Austrian war, sixty-six per cent. In the American civil war the mortality was 62.5 per cent. This reduced mortality-rate is, according to Santi, due to the smaller size of projectiles now used. This writer believes that in the case of wounds of the chest, from a ball of small calibre, which have been antiseptically treated, the mortality should not be greater than fifteen per cent.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 15, 1892.

TACHYCARDIA.

THE term tachycardia has recently come to be somewhat loosely employed in describing various conditions associated with rapid heart action, and confusion might readily arise from failure to distinguish the essential paroxysmal tachycardia described by Bouveret, from that which is symptomatic. One author has even defined tachycardia as "a disease without demonstrable organic heart-lesion," while, as is well known, it is rather to be looked upon as a symptom in many pathological states of different nature and location, besides the neurosis upon which the essential variety is supposed to depend.

Were exact knowledge always obtainable, the latter form of tachycardia would probably be found much more rarely than instances in which some lesion of an organic nature is present, either within the confines of the heart-walls, or, as in an instance just reported, involving the pericardium, or in some organ more or less intimately connected with the heart. Instances are recorded in which paroxysmal rhythmic disturbances, and great acceleration of the heart-stroke, have followed injuries, such as a fall upon the head; and some such cases seem to be more properly classed as tachycardia than as cardiac epilepsy, while essential tachycardia has a counterpart in the heart derangement occasionally observed in epilepsy itself.

In "Basedow's disease," too, a certain proportion of the sufferers are tachycardiacs, and here, by the way, according to Eloy, the paroxysms are greatly diminished by hydrotherapy.

In cardiac hypertrophy, especially that form which is found associated with chloro-anæmia, paroxysms of tachycardia are prone to occur, and while in the vast majority of heart affections such attacks are not among the prominent symptoms, care must be exercised to separate such symptomatic cases from the essential variety. This, as has been previously intimated, is not always an easy matter, and even after death, without microscopic examination, or even with it, affections of the ganglia of the heart, or the nervi accelerantes, or other changes in the myocardium might pass unnoticed.

Where there are plainly marked endocardial changes, or valvular lesions, a tachycardia can be readily explained as due to reflex irritation. The writer has had a case under observation for a number of years in which a valvular stenosis caused the patient scarcely any other trouble than an occasional severe paroxysm o tachycardia lasting from ten minutes to twelve hours and during which the heart-beats could only be approxi mated at from two to three hundred in the minute. Thi patient can almost always stop the palpitation, after it ha been going on for some time, by allowing the head to hang down over the side of the lounge or bed, until i nearly reaches the floor. The rapid beating will then stop with a sudden and somewhat painful thud, felt in al parts of the body, after which the pulsations become a once perfectly regular at from eighty to a hundred in the minute.

Treatment is without much avail in most tachycardias whether they be due to paralysis of the inhibitory fibre of the pneumogastric, to irritation of the accelerators o the sympathetic, or to reflex action from some lesion i the heart-wall or elsewhere. Morphine is probably th best remedy during the attack, given beneath the skin t insure prompt action. Quinine, ergot, and nux vomic have been well spoken of in the intervals, and digitalis i almost always useful.

Brannan, in an excellent paper read last year at th Academy, says that caffeine, nitro-glycerine, and nitrite o amyl have no effect. He cites the case of Nothnagel' patient, who could retard the paroxysm by holding th breath as long as possible, and that of Wood, who stoppe the attack by drinking fluid as rapidly as she could, an either very cold or as hot as it could be swallowed Poulet has found benefit from a twenty per cent. tinctur of the *coronilla varia*, a plant very common in Alsace, whic resembles digitalis in its action. Fifteen to thirty drop are to be given daily.

Cure of this condition is very exceptional, but Dr Hampeln has just reported an instance of habitual an paroxysmal tachycardia of fifteen years' standing, whic resulted in natural recovery. The case, which is de scribed in the *Deutsche Medic. Wochenschrift*, Septem ber 1, 1892, has an additional interest on etiologica grounds. The patient had been attacked fifteen year before with acute articular rheumatism, and had as a complication severe fibrino-serous pericarditis. The at tacks of tachycardia, with pulse reaching 280 beats, dysp nœa, etc., had then come on, and gradually increased i duration from three-quarters of an hour to eight hours when in April, 1891, after an unusually severe paroxysm the heart suddenly regained its natural beat, and has sinc remained free from any evidence of the former trouble.

The author's explanation is that attachments had bee occasioned by the pericarditis, and that these interfere with the freedom of the heart's action and acted as a constant excitant from the mechanical restraint. In th last severe paroxysm these attachments were supposed t have been torn away, or so stretched that they no longe acted as fetters upon the organ, which once freed fro its restraining and irritating bonds, sank into the quie and regular action of fifteen years before. In few in stances could such a happy termination be hoped for but the record is encouraging as showing that recovery possible, even after many years and in very severe cases as this one undoubtedly was. In essential tachycard the most that can be accomplished is to secure all th freedom from nerve-irritation and fatigue which is pos sible, and with this end in view stimulants and tobacc

will be withheld. Digitalis, in form and dose to meet the requirements of the case, will be the drug from which most benefit will probably be found, and during the attack, on account of gastric intolerance, it may be given hypodermically or, as Huchard has suggested, by the rectum.

VIVISECTION AGAIN.

THERE is a paper called *Our Animal Friends*. It is professedly addressed to the general public, and to the younger and perhaps kindlier portion of that public. Its object is no doubt a good one, and it has our best wishes in its efforts to develop humanity and gentleness toward animals.

When such a paper, however, deliberately publishes flagrant lies about medical men and their work, it deserves the severest reprobation, for it betrays its trust and misuses its position as a promoter of morals. In its issue for July is an article on vivisection of the hysterical character usual to professional antivivisectionists. If it were simply this, however, we might let it pass; but the tone of it is grossly misleading and many statements are untrue. For example it says: "We have before us a list of two hundred and twenty-seven cases of hydrophobia treated by M. Pasteur from September, 1885, to February 4, 1892. Every one of those cases terminated in death. In one of them, the patient, who was himself a physician, went to Paris for treatment, and died of hydrophobia two years and two months afterward. Against this more than double hecatomb of victims of hydrophobia—many of which may well have been victims of the 'inoculations'—M. Pasteur can point to *not one case* of alleged cure by his treatment, in which the virus of rabies had certainly entered the system of the victim. It appears, then, that to this day there is absolutely not one particle of evidence that the unspeakable torture of scores of thousands of inoffensive creatures, put to death by M. Pasteur and his followers, with all the agonies of hydrophobia, has saved one single human life!"

As a matter of fact, between 1886 and 1891, 9,465 persons were treated by Pasteur for rabies and 90 died. A mortality of less than one per cent. Since at a very low estimate the normal mortality would be 946, Pasteur may be credited with saving over 800 lives, instead of losing 297.

Among other extraordinary statements made in the same article are these: "Medical men boast that they are ministers of humanity, and yet a large part of their training is such as to make them remorselessly inhuman." It would be easy to fill hundreds of numbers of *Our Animal Friends* with illustrations of the absolute inutility of thousands of experiments which are continually and wantonly repeated under the false pretence of scientific research."

Our Animal Friends is, we believe, the organ of the Society for the Prevention of Cruelty to Animals, and it estimates that the Society should undertake a systematic propaganda in this State in order to abolish vivisection.

We note that its list of officers contains five or six lawyers and one clergyman, but no physician. We would suggest that it secure the service of some medical man who might temper the rhetoric of its editor with truth and justice. The fact is that the amount of vivisection done in this country is very small. It would be better for humanity if it were more encouraged. No single agent is doing more to banish disease, and with it sin and unhappiness, from mankind.

THE PAIN OF DEATH.

THE question whether death is a pleasant or painless process has been agitated in the columns of the *Sun*, and several very exciting accounts of the sensations of the dying have been reported. The conclusion is reached that death, on the whole, furnishes an agreeable sensation and one not to be dreaded. "A great thing this, Lucilius," says Seneca, "and worthy of long study, namely, that a man quit life with tranquil spirit when that inevitable moment comes." "To fear death," he adds, "is foolish. Death imposes a necessity that is impartial and inevitable. Who can grumble at being subject to a condition from which no one is exempt." Thus the ancient Stoic reasons, until between him and the *Sun* correspondents one might be quite persuaded to look upon death as an agreeable diversion. Unhappily, the assurances of the experienced and the philosophy of the wise are of little aid when the actual exigency confronts us. Medical observation shows that as death approaches one in old age, the sensibilities become benumbed and the process, if not agreeable, is not painful. The natural death of the aged is a physiological phenomenon, and should excite no apprehension as it involves no distress. The onset of death in the younger and healthy persons is viewed with a natural apprehension which can only be modified by temperament and the consolations of religion and philosophy.

The question whether the actual act of dying is painful cannot be answered categorically; for we do not know when a person dies, but only when he loses consciousness. The point discussed in the *Sun* is, therefore, really whether losing consciousness is painful. We believe that the experience of most physicians would affirm that it is. Ordinary syncope, epileptic attacks, the production of anæsthesia, the results of a cerebral concussion are usually not described as agreeable. The sensations of those drowning and asphyxiated, on the other hand, seem to be more often pleasant, at least in the later stages. Certain narcotic poisons can also produce coma agreeably. But, on the whole, man feels best when consciousness is clear and well preserved, and its sudden loss is attended with more pain than pleasure.

A NEW TEST FOR GLANDERS.

THE appearance of glanders in London, and in this city lends special interest to recent bacteriological studies of this disease which have resulted in furnishing a diagnostic test. A year and a half ago, Dr. Kalning, of Dorpat, announced that he had prepared an extract from the bacillus of glanders (b. mallei) which caused a febrile reaction when injected into infected animals. Dr. Kalning unhappily caught glanders and died in the course of his experiments. Dr. Preusse, of Dantzic, Dr. Pearson, of Berlin, and Professor Nocard, of Paris, all working independently, have reached similar results to those of Dr.

Kalming. Preusse's method has been most largely followed and tested (*British Medical Journal*). He used old, dried-up cultures of the bacillus mallei grown on potato; these he steeped for several days in a mixture of water and glycerine (equal parts), at the temperature of the body. The extract he filtered several times, and sterilized in the steam bath. It was finally an imperfectly clear, dark yellow, oily liquid, of neutral or faintly acid reaction; it possessed a characteristic odor. Preusse tried the action of this extract on six horses belonging to certain large stables in which glanders had just previously broken out; none of the six horses, however, showed at the time of his experiments any unequivocal sign of being themselves glandered. All but one showed febrile reaction in five to fifteen hours. The horses were killed in twenty-four hours and all those which had had the fever showed the unmistakable evidence of glanders.

Altogether 64 horses have been tested by Preusse's method. Of these, one animal was obviously at the time of injection glandered, but the remaining 63 showed at that time no definite symptoms of the disease. In 41 of the horses a first injection of mallein was followed in about eight hours, and a second in about four hours, by an elevation of temperature altogether above the limits of the normal. In 23 horses no rise of temperature whatever followed the injection. Every one of these 23 cases proved on *post-mortem* examination to be completely free from anatomical signs of glanders. Of the 41 horses which gave a febrile reaction after injection, 38 were found by *post-mortem* examination to be actually glandered, but in 2 of the 41 the most careful scrutiny failed to reveal any signs at all of a glanderous condition. The test has been used somewhat in London, but not yet with perfect satisfaction. If the disease spreads in this city or neighborhood it is to be hoped that some of the testing extracts will be tried.

THE TREATMENT OF AORTIC ANEURISM.

It is to be hoped that the ingenuity and perseverance shown by surgeons and physicians in their attempts to cure aneurism of the large arteries will be eventually successful. The history of the therapeutics of this trouble is extremely interesting, but also very disappointing. The ancient and heroic methods of ligation illustrated how near a bold surgeon could get to the heart without killing the patient at once; the operations were successful, perhaps, but the patient died. The attempts of surgeons have in late years been directed mostly to some method of producing mechanically coagulation of the sac. At first, the galvanic current was tried, then foreign bodies, as wire or catgut, were introduced. Not long ago Macewen advised the practice of scratching the inner surface of the sac with needles. A combination of the galvanic current and a long wire has been tried several times. In the *American Journal of the Medical Sciences* for October, Dr. D. D. Stewart reviews the results of this mode of treatment and contributes a case of his own, making a total of eight. Of these eight, six died and two were improved or cured. In most of the six fatal cases the operation was not attempted until the patient was in a hopeless condition. Furthermore, Dr. Stewart shows that the technique has usually been imperfect, and his observations lead one to hope that with greater experience and skill we may yet be able to relieve many heretofore hopeless cases. Dr. Stewart advises the use of silver wire in preference to steel, soft iron, or catgut. The wire should be fine and should be drawn just sufficiently hard to be readily passed through the cannula forming spirals in the sac. It is believed that six to ten feet of wire are sufficient. A strong galvanic current of 50 to 70 milliampères should be passed through the aneurism for an hour, the anode being attached to the intra-aneurismal coil.

CHARAKA SAMHITA.

It may be that some readers are weary at times of the medicine of to-day, with its arid science, its disappointing art, and the politics of its prophylaxis. If so we commend them to "Charaka Samhitá," a treatise on Hindu medicine which has recently been put in English by Dr. Abinash Chandra Kaviratna. This treatise comes in parts or lessons, and takes us into new realms of medical thought and new modes of scientific teaching. The right of translation is reserved, but we can give a little idea perhaps of how Lesson III. appears in modern English.

According to the "Samhita," Aragbadhiya, son of Atri revered by Siddhas and great Rishis, has described for the benefit of the world two and thirty kinds of powders and plasters that destroy divers diseases. The son of Atri has also gone briefly—yet not too briefly—over six centuries of purgatives, and for the benefit of many ascetics, crowned with high success in the mysteries of faking and purging, he has described six hundred kinds of purgatives. As there are six hundred purgatives, so there are, says the son of Atri, five hundred astringents of which only fifty are *par excellence*, or, so to speak good for something. Now, as a brief account would not be suitable for persons of little intelligence, and a long account would not be printed, Aragbadhiya proceeds to give an account which is neither short nor long, which ingenious course goes to his credit in "Karma." Such at least would seem proper and just; but Aquiveca, his pupil, said: "O, illustrious Rishi, of the fifty really good astringents, forty, as I perceive, are just the same things with a different name;" to which the son of Atri replies in effect that a person of intelligence will not criticise his master, or trifle with the grandson of Charaka Samhita. The six hundred purgatives are made, says the Science of Life, for the six different kinds of constipation. One hundred for each kind, and the five hundred astringents for the six different kinds of tastes, one for each taste and one for a change. Here the illustrious son of Atri publishes some verses, and then expounds the lesson called Matracituja, which is the Science of Diet.

Now, concerning this, the light of Asia, and father of cholera, namely, the son of Atri, affirms that food taken in due measure, without injuring the constitution or taking the six hundred purgatives, certainly bestows strength, color, health, and length of days. Says the master: "One should not, with loaded stomach take such heavy diet as cakes and similar preparations, and unhusked paddies. With even an empty stomach, these should be taken in proper measure. Dried meat, dried potherbs, esculent roots of the nymphæa lotus and the

stalks of the water-lily, should not be taken as habitual diet, in consequence of these being heavy. Nor should one take the meat of a lean, diseased or dead animal." The reason for this preference for live animals and this proscription of paddies is then given in more detail than we have space to furnish our perhaps already impatient readers.

The "Charaka Samhita" is being published in regular instalments, and it is not all out as yet. Hence the fragmentary character of the specimens we have given.

News of the Week.

The Babies' Hospital.—Dr. A. Blair Thaw, of New York, has given $10,000 to the hospital for the erection at Seabright, N. J., of a cottage to be used as a country branch during the summer. The corner-stone was laid on September 24th, with appropriate ceremonies, including addresses by Drs. A. H. Smith, E. L. Keyes, R. B. Kimball, and others. The country hospital will have twenty-eight beds, and will be ready for use next season.

"The Circle of Willis," the first social organization of the united professions, held its opening reception in their club-house on the evening of October 6th. There was a large attendance. The opening address of welcome by Dr. Frank A. McGuire, the presiding officer, and known as the Grand Chief Demonstrator, touched upon the emancipation of the Doctor socially, his relation to the laity, with patriotic allusions to the Columbian celebration. He was followed by Dr. W. B. Wallace, Dr. Chas. Milne, Dr. Julius A. Roth, Dr. E. Sander, Dr. Wm. Deane, D.D.S., Thos. E. Fraser, Ph.D., E. Schyer, and Counsellor Mayer, with recitations and singing by Mr. Ed. Stanley, of the DeWolf Hopper Opera Co., and others. A feature of the occasion was the presentation of the Anatomical Circle of Willis by Dr. Irving Haynes, Demonstrator of Anatomy in the University Medical College, which was framed, and occupied a prominent position on the walls; with also an original copy of the "Anatomy" of Dr. Willis, over two hundred years old, presented by Dr. N. E. Brill, President of the Society of Medical Jurisprudence and State Medicine. A collation was served with the usual social amenities which obtain on such occasions.

We trust that the Circle of Willis will always maintain its proper circulatory equilibrium, that no stray embolus, intrusive thrombus, or escaping clot may disturb the harmony of its tributary resources.

Do Doctors Get Cholera?—The impression that the physicians who attend cholera patients do not get the disease is not well founded. Of the fifty doctors who went to Hamburg to assist in the work there, hardly one, we are told, escaped a more or less severe choleraic attack.

Cholera and Fright.—Miss Annesley Kenealy writes from a Hamburg Hospital to the *British Medical Journal*: "It has been said that at least two-thirds of cholera patients die of fright, but the experiences on which this opinion were founded were gathered in India, where it is doubtless true. Though possible in the highly nervous Hindu, it is not easy to believe of the phlegmatic German; yet some of these people have a stricken, startled stare. The delirium or lethargic drowsiness, both of which are common, show that the disease makes some special attack upon the nervous system. It is stated that the brain and nervous centres are being now more affected than in the earlier days of the epidemic. I have seen two cases of absolute dementia resulting from cholera, the patient being perfectly imbecile and apathetic, looking with vacant, meaningless eyes, the features pinched, the complexion dusky, the temperature persistently and considerably below the normal. In both cases—which ended fatally—there was the utmost difficulty in persuading the women to take food. Some of the patients shriek wildly, and at the top of their voices day and night."

The Treatment of Cholera at Hamburg.—The Hamburg correspondent of the *British Medical Journal* states that Dr. Rieder, assistant at the *Allgemeine Krankenhaus*, has found tannin enemata prove totally ineffective, it is also the case with the administration of camphor, ether, and salol by the mouth. Subcutaneous injections of salt solution did good in some cases, but the greatest benefit was derived from intravenous infusions of salt solution.

Elective Cæsarean Section.—On September 28th, at the Kensington Hospital for Women, Philadelphia, Dr. Charles P. Noble performed Cæsarean section on a primipara having a scolio-rachitic flat pelvis, with a true conjugate, estimated at two and three-quarter inches. The woman being at full term, the operation was done at a selected hour instead of permitting her to fall in labor. This makes the fourth Cæsarean section done in this hospital, and the sixth done by the surgeons of the hospital. All the previous cases have recovered. In the recent case the mother and daughter are doing well.

Changes of Address.—Much as we should desire to please our subscribers it has been found impossible to respond to the numerous requests to publish changes of address.

The Board of Health of Savannah, Ga., has adopted a new and sensible plan for securing a quarantine officer at that port. Notice was given that examinations of applicants for the position would be held in New York, Philadelphia, Savannah, and New Orleans, the successful candidate to receive $2,000 per annum salary and to hold the office for three years. The examination required the name, age, residence, college, the date of graduation, a statement of the hospital experience, if any, whether the candidate was subject to sea sickness, and his experience in microscopy and bacteriology.

Doctors as Popular Leaders.—A statement having been made in a German professional work to the effect that Mr. Gladstone had prophesied that doctors would become the leaders of the people, a correspondent wrote to the Prime Minister for the purpose of ascertaining the truth of the matter. In reply Mr. Gladstone said: "So far as regards the exact words cited in your letter, I cannot positively say aye or no, and I rather think that I should in using them have added some qualifying or limited expressions. But it is certainly a fact that for a very long time I have believed the medical profession to be both in a state of absolute advance from the progress of its science—this, it may be said, is mere commonplace—and of relative advance from the particular features attaching to our civilization in its onward movement."

Dr. William Macewen has been made Surgeon to the Royal Infirmary at Glasgow, and Regent Professor of Surgery to the University of Glasgow.

The New York State Association of Railway Surgeons will hold its Second Annual Meeting at the Academy of Medicine, 17 West Forty-third Street, New York, on November 14, 1892. The profession is cordially invited.

Dr. W. A. Wile, of Danbury, Conn., has been elected Surgeon-General of the G. A. R.

Dr. Reynold W. Wilcox, of this city, has been elected Surgeon-General of the Sons of Veterans.

A New Treatment of Oöphoro-salpingitis.—Every practitioner is aware of the unsatisfactory means at our disposal (short of abdominal section) for the treatment of the above condition. At the best, in most cases, the patient is relieved of the acute symptoms, leaving the disease in a chronic stage for a weary length of time. Dr. Auvard, of Paris, announces the successful treatment of two cases by means of intermittent pressure, which he applies in the following manner: A Gariel air-pessary is introduced into the vagina and a bag filled with shot is simultaneously maintained over the site of the abdominal induration. The weight of the shot is gradually increased from 750 to 1,500 grammes, and the bag is kept applied for from two to three hours every morning and evening. During the interval (the pessary being also removed) hot vaginal injections and a cold enema are administered. In one case quoted, where a very tender swelling the size of a hen's egg could be felt in the right broad ligament, the tumefaction had completely disappeared after ten days of this treatment, and in three weeks the woman was well. In another case of oöphoro-salpingitis induced by intra-uterine exploration, internal and external intermittent pressure, by means of a Gariel pessary and a shot-bag weighing one kilogramme, practised once daily for an hour and a half, relieved all the suffering and greatly reduced the swelling.—*Lancet.*

Eleventh International Congress.—As a recent notice in the MEDICAL RECORD has informed our readers, the Eleventh International Congress will meet in Rome, Italy, from September 24, to October 1, 1893. By an official letter dated August 22, 1892, and signed by Professor Guido Baccelli, President, and Professor E. Maragliano, Secretary-General, Dr. A. Jacobi, of New York, has been directed to form an American Sub-committee. Its membership is not yet complete, but on it are already found, beside that of the Chairman, the names of Drs. William Osler, of Baltimore, S. C. Busey, of Washington, N. S. Davis, of Chicago, Charles A. L. Reed, of Cincinnati, William Pepper, of Philadelphia, F. Peyre Porcher, of Charleston, James Stewart, of Montreal, and Alexander J. C. Skene, of Brooklyn, N. Y. In the interest of facilitating the trip to Italy, and reducing the expense, arrangements will be made with the steamship companies. According to a communication from the Central Committee—contained in a letter of the Secretary-General's dated September 14th—the North German Lloyd proposes to reduce the fare to Genoa by twenty per cent., and that of the return trip by ten per cent. It is expected that still more favorable terms will be secured.

Quarantine in Canada.—At the recent meeting of the Canadian Medical Association, held at Ottawa, resolutions were adopted calling for the appointment of a pe manent executive, whose duties it will be to supervise matters relating to the public health. It was also urg that houses of observation and detention of suspects, a hospitals for treatment of sick, be supplied and equipp at Niagara and similar border points; and further, th all passenger ships should be provided with all necessa apparatus for the disinfection of baggage and clothin with isolation rooms for the treatment of those sick suspected contagious disease, and with apparatus f sterilizing the drinking-water. Resolutions were al adopted calling upon the government to put the quara tine station at Grosse Isle in perfect order, and equip with all the appliances necessary to meet every possil emergency. Finally, it was suggested that, in view of t imminent danger of cholera reaching America in 18 the government should consider the expediency of pr venting immigration to Canada from infected countri

Eighty-two Cents a Day.—A private telegram fro Halle, recently published in the *Berliner Tagbla* stated that several physicians (who, in response to t appeal made by the Hamburg authorities for ext medical assistance, undertook service in that city witho having stipulated definite terms) were offered 3s. 6d. their daily remuneration, whereas laborers engaged f the transport of the sick are being paid at the rate 15s. per day! On refusing such a preposterous offer t doctors in question, the writer says, were abruptly d missed without a word of thanks.

Dr. Charles E. Sajous, of Philadelphia, editor of *T Medical Annual,* has been named a Knight of the Legi of Honor by M. Carnot, in recognition of his servic to the French colony in Philadelphia. Dr. Sajous is French descent.

The Singing-master and Modern Physiology.—T latter-day singing-master is nothing if not scientific, sa *The British Medical Journal,* and his acquaintance wi the anatomy of the vocal organs is as extensive, a sometimes as peculiar, as Sam Weller's knowledge London. The following extract from an "imagina conversation" (not by Walter Savage Landor, but by anonymous American humorist) amusingly illustrates t effect likely to be produced on the untutored mind the scientific jargon affected by our "up-to-date" pr fessors of singing. A lady, who had taken her daugh to have her voice tried by several of these superior p sons, returned home much discouraged, and gave the f lowing report to her husband: "The first professor sa that Almira sings too much with her borax. If she kee on she will get digestion of the lungs. He said s ought to try the abominable breathing and practise s fudgery. Then the next teacher told me she ought sing with her diagram, and not smother her voice in t sarcophagus. Then the next he poked a looking-gl down her throat and said the phalanx was too small, a the typhoid bone and the polyglottis were in a bad wa and I never knew that Almira had so many things down h throat, and I am afraid to let her sing any more for fea will kill the poor girl." We may laugh at this poor M Malaprop, but her experience points a moral which m be commended to the attention of those who undertake train the voice by the light of the laryngoscopic lamp.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 25, 1892.

H. P. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Solitary Tubercle of the Suprarenal Capsule.—DR. MARTHA WOLLSTEIN exhibited under the microscope a specimen showing a rather unusual form of tuberculosis of the suprarenal capsule. The specimen had been taken from a child of ten weeks, who had been admitted to the Babies' Hospital a short time before death with symptoms of dyspepsia and malnutrition. The child had been nursed only one month, and then fed on cow's milk for two weeks previous to admission. There was a decidedly phthisical family history. At the autopsy the brain was found to be normal; there were miliary tubercles in the lungs, and a cavity in the left apex containing greenish pus. The bronchial glands were moderately enlarged, and many of them were cheesy; there were tubercles in the liver and spleen, but nothing was found in the kidneys except uric-acid infarctions. The suprarenal capsules were normal in size, and apparently so on section, as were also the stomach, intestines, and mesenteric glands. Sections from the lungs showed acute miliary tuberculosis, the distribution being for the most part peri-bronchial. The sections from the bronchial glands showed conglomerate tubercles, and as the entire centre of the nodule was cheesy, it was impossible to say whether the poison had been brought to the nodules by the lymph current, or by the blood. In the medullary portion of the suprarenal capsule, beyond the point reached by the incision, was one small tubercle, and some of the sections from this portion showed small round cells, and others single giant-cells, but no tubercle bacilli were present.

The presence of such a single, discrete tubercle in the suprarenal capsule is quite rare, large cheesy masses being usually present. The specimen evidently illustrated a very early stage of tuberculosis of this organ, and the situation in the medulla was explained by the greater vascularity of that portion. From the amount of peri-bronchitis present, it is probable that the tubercle bacilli gained entrance through the lungs by aspiration, and that then the lymph-nodules of the spleen, liver, and supra-renal capsules became successively infected. The healthy condition of the entire alimentary tract negatives the idea that the tubercular infection had its origin in the child's food.

Carcinoma of the Breast Following Traumatism.—DR. R. H. SAVRE presented gross and microscopical specimens from a case of carcinoma of the breast which gave a rather strange history. The woman was thirty-eight years of age, and the chest-walls indicated that she had been the subject of rachitis in her youth. There was no family history of malignant disease, except that the grandfather had had an epithelioma of the lip. In November, 1890, while carrying a heavy load of dishes, she fell, and was struck in the thorax by some of the falling dishes. She was examined by a physician, who expressed the opinion that she had sustained a fracture at the junction of the costal cartilage with the fourth rib, on the right side. In May, 1891, she again fell and injured the breast on the right side. This was followed by pain in the breast, and the appearance of a line of induration and swelling extending from the site of the first injury to the nipple. Some time after this she also noticed a small nodule in the lower part of the breast. In March, 1892, after a slight blow on the same breast, a yellowish pus began to discharge from the nipple, and this continued up to the time when she first came under the speaker's observation. An examination of this discharge showed no tubercle bacilli present. The breast was removed, together with one enlarged axillary gland. There was a small nodule in the lower part of the gland, and another in the upper portion. Below the pectoralis major muscle was a sinus containing pus, and leading up to the fourth rib, where there was some dead bone. Another sinus extended from this point to the nipple. Microscopical examination showed the nodules in the breast to be carcinomatous. The case was interesting on account of the possible connection between the traumatism and the development of the carcinoma.

Demonstration of the Amœba Dysenteriæ in the Tissues.—DR. J. S. ELY demonstrated under the microscope the amœba dysenteriæ in the ulcers of the colon and in an abscess of the liver. The material had been kindly furnished him by Dr. J. W. Brannan, and was particularly interesting as the specimens had been taken from the remarkable case of recurrent abscesses of the liver which had been recently reported to the Society by Dr. Edebohls. Dr. Ely said that the whole subject had been so carefully worked out and described in an excellent monograph by Drs. Councilman and Lafleur, of the Johns Hopkins University, that additional comment was unnecessary. The speaker said that on a previous occasion he had found this amœba in the stools of a patient, but, so far as he knew, this was the first time observers in this locality had had an opportunity of seeing the amœbæ in the tissues. The specimen had been stained with the ordinary double stain of hæmatoxylin and eosin.

Diffuse Infiltrating Sarcoma of the Heart.—THE PRESIDENT presented gross and microscopical specimens which had been removed from a single lady, twenty-five years of age, who entered the New York Cancer Hospital for the purpose of having an excessively hypertrophied breast removed. Her general health was good. The enlargement of the breast was of rapid growth, uniform, non-nodular, and but slightly painful. Before the operation was undertaken she developed a low form of fever, accompanied by intense dyspnœa and some delirium. She died suddenly at the end of the fourth week. The case being of peculiar interest was examined by a number of physicians. Those who ventured a diagnosis pronounced the disease typhoid fever. There was no eruption or enlargement of the spleen. The autopsy was made twenty-four hours after death, and at this time rigor mortis was present. Both breasts were enlarged, one to about four times the size of a normal breast. The body was well nourished, and there was an abundance of subcutaneous fat. The pericardium was distended with a sanguineous fluid, and the visceral layer was covered with a plastic exudation. The heart was hypertrophied, weighing sixteen ounces. There was no valvular lesion, but the cavity of the left ventricle was dilated. The walls of both ventricles were increased in size; the left measured 1½ ctm.; the right, ½ ctm. They were of a light-gray color, and softer than normal. The walls of the auricles were also increased in thickness. The coronary arteries were normal. The lungs, with the exception of pulmonary œdema and congestion, were normal. The liver was normal in size, and presented the "nut-meg" appearance. The spleen was normal. The kidneys were enormously enlarged, measuring six to eight inches in length; their capsules were non-adherent, they were softer than normal, and of a light-yellow color. On section, the cortex was increased in thickness and the markings gone. The kidney presented the gross appearance of the "granulo-fatty kidney." An examination of the intestines revealed nothing abnormal; there were no typhoid ulcers. A few of the mesenteric glands were enlarged to the size of an olive, and the only lesion found in them on microscopical examination was hyaline degeneration of the capillaries.

The microscopical examination of the heart-muscle and of the kidneys revealed a most peculiar and interesting condition. Between the muscle-fibres of the heart were cells, larger and differing in appearance from pus-cells, or the cells of early connective-tissue formation. These cells were arranged in rows, or packed together

between the muscle-fibres. These cells were found between all the muscle-fibres, which showed the effect of the compression by a certain amount of degeneration. Sections were cut from different places on both sides of the heart, and the same changes were found in all. Staining by Gram's method for micro-organisms reveal ed none of these organisms. A microscopical examination of different portions of the cortex of the kidney showed the renal tissue everywhere packed with these peculiar cells. Among the cells could be seen the compressed tubules. The capillaries of the glomeruli were normal, and contained none of these cells. No micro-organisms were present. In a very few places between the cells a delicate fibrinous stroma could apparently be discovered.

The speaker said that he had never before seen such condition in the heart or kidneys, and the only conditions which could account for the microscopical appearances already described were diffuse suppurative myocarditis, nephritis, diffuse round cell infiltration, and diffuse infiltrating sarcoma. He believed it to be the last, as the cells were like the round cells of sarcoma, and between them in places was an intercellular substance. The enlargement of the breast he believed to be due to a rapidly infiltrating round-cell sarcoma. By metastasis the heart and kidneys were secondarily involved. Next, a pericarditis was developed. The excessive dyspnœa and the sudden death were explained by the cellular infiltration interfering with and compressing the muscle-fibres of the heart; in fact, it seemed surprising that such a heart could beat at all. Unfortunately, pieces of the breast were not removed for microscopical examination. A careful study of the literature of diseases of the heart-walls has aided but little in understanding this case. Sarcoma of the heart, even as a secondary affection, is a rare condition, and when it occurs it is generally circumscribed. Orth speaks of a rapidly advancing sarcoma infiltrating the walls of both ventricles without producing a tumor. Drs. Prudden and Biggs had examined the specimens, and had stated that they had never met with this condition before. The former believed the lesion to be sarcomatous, and the latter was inclined to look upon it as a diffuse suppuration.

Dr. S. T. Armstrong said that the case reminded him of a similar one which had come under his observation while in command of the Marine Hospital at Memphis, and which was published in the "Annual Report of the United States Marine Hospital Service for 1886." The patient was a negro, who when first admitted had some bronchial symptoms, which were succeeded by diarrhœa. He was under treatment for about two weeks previous to his death, and the case was at first looked upon as one of typhoid fever. At the autopsy two tumors were found in the brain, which seemed to have developed in the pia mater, one in the right frontal lobe and the other in the left side of the cerebellum. The only other abnormality observed at the autopsy was an enlargement of the lymphatic glands, and of the liver, spleen, kidneys, and suprarenal capsules. Sections were made of all these organs, and microscopical examination showed the same round-cell infiltration observable in the specimens just exhibited under the microscope. His case was reported as one of lymphadenoma, or that variety of lympho-sarcoma which involves the glandular organs of the body.

Dr. J. M. Byron said that he recalled seeing in medical literature a report of a number of cases of diffuse infiltration of the heart and other organs by metastatic malignant growths, but he had not seen or heard of anything just like the case under discussion. The specimens under the microscope possessed no reticulated tissue, or any of the characters which would characterize it as a sarcoma, and the cells were much larger and flatter than those seen in a small round-cell sarcoma; in fact, they resembled the "infant cells" of endothelioma.

Dr. J. S. Ely thought that the grouping of the cells in concentric layers around the blood vessels was characteristic of endothelioma.

Lobar Pneumonia, Possibly of Microbic Origin.—Dr. J. Lewis Smith presented specimens from a case of pneumonia occurring in a child, three and one-half years old. The child was an inmate of an institution where there had been during the past winter an unusually large number of cases of pneumonia of uncommon severity. The ravages of the disease in this hospital had been so great in contrast with those in another institution with which Dr. Smith was also connected, that he had been led to believe that the pneumonia in the former place might be of microbic origin. The specimens presented were from a case which fairly illustrated the type of the disease. He hoped an examination by the Microscopical Committee would throw some light upon the etiology. The child had been in good health up to May 9, 1892, when the temperature suddenly rose to 105° F., the respirations to 60, and the pulse was correspondingly increased in frequency. There was also some cough. Within twenty-four hours the disease could be located in the left upper lobe by the bronchial respiration and dulness over this area. After about a week the disease appeared to be about to resolve, when the opposite lung became similarly affected over its upper portion. The child died yesterday of heart-failure, with a pulse of 180, and a temperature of 105° F. The rapid onset and the absence of a previous bronchitis would seem to indicate that the disease was lobar rather than lobular.

The Microscopical Committee was requested to report upon the specimen at the next meeting.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE SANITARY CONGRESS—THE CHOLERA—SANITATION OF DWELLING-HOUSES—DEATH OF MR. EDWARD COCK.

London, September 17, 1892.

The Thirteenth Annual Congress of the Sanitary Institute has been held at Portsmouth during the past week. Sir Charles Cameron, of Dublin, presided, and delivered an address in which he drew attention to the continuous progress in sanitation and steady fall in death-rates which had taken place during the Victorian era. The death-rate in London had been declining in spite of the increasing concentration of the population. In 1841 there were but twenty-five persons to the acre; in 1891 there were fifty-six per acre. In London, however, the unfavorable influence of the increased density of population was much more than compensated for by the great improvements which had been effected in the general hygienic conditions. Speaking of typhoid fever in Dublin, Sir Charles Cameron said he had come to the conclusion that there, and perhaps elsewhere, it was miasmatic, or earth-born. In Dublin during the last decade one person in one hundred and forty-four living on clay soils had typhoid fever, and one in every ninety-two living on gravels. The disengagement of the micro-organisms of the disease took place when the soils became dry, and this occurred more frequently with gravel than with clay. When all the organic *débris* produced in towns was quickly removed, and when the dangerous subterranean atmosphere was prevented from entering our dwellings, or even our streets, when sewage flowed steadily day and night through well constructed main sewers, and when our soils were thoroughly drained, and kept free from filth, then we might expect to see a substantial reduction in the mortality caused by typhoid fever, and, indeed, by other diseases. He urged the adoption of a triennial census, and remarked on the importance and utility of vital and moral statistics. The recent reduction in the death-rate, he said, was most marked in the case of infective diseases, of which phthisis was the most fatal. We should not be discouraged because of Koch's failure to destroy the tubercle bacillus; in time we should be

le to control its ravages and perhaps to extirpate it altogether.

The sectional proceedings commenced on the second y of the Congress. Professor Kelly read a paper on the nsus, in which he advocated a quinquennial one. Dr. oves read a paper on "Isolation Hospitals." After s had been read and discussed, the following resolution s proposed and unanimously carried: "That the Sani- y Institute be recommended to ask the Local Govern- nt Board to allow a special expenditure for cholera pre- itions and hospitals, and that such expenditure should me out of the Imperial and not out of the local rates." . Fairchild read a paper on "Difficulties in the Pre- ition of Infectious Diseases," in which he pointed out t the notification of infectious diseases by the head of e family was seldom carried out in many districts, and reby delay was caused in the taking of proper steps by sanitary authority. A resolution was moved by Mr. discott, seconded by Mr. Fairchild, and carried unani- usly, "That this meeting is of opinion that the removal an isolation hospital of all persons, irrespective of social tus, who are not, in the opinion of the sanitary officers, ctually isolated, should be made compulsory." Dr. beck Nevius read a paper in which he endeavored to w that the abolition of the Contagious Diseases Acts had l no injurious influence on the public health; his statis s were, however, disputed by the President and others. paper by Dr. Harris, advocating the compulsory treat- nt of phthisis, did not meet with a more favorable re- tion; those who took part in the discussion maintained t more good would be done by medical officers becom- popular educators in matters affecting the public health. a communication from Dr. Newsholme the condem- ion of the meat of tuberculous animals was recom- nded as a precautionary measure; a resolution recom nding that where a portion of an animal was affected h disease the whole carcass should be condemned was sequently carried unanimously.

On Wednesday Professor Notter, of Netley, took the air in the Section of Sanitary Science and Preventive dicine, and, dwelling on the danger of cholera, warned itary authorities to look to crowded areas. A discus- n then took place on tuberculosis and its causation by ing tuberculous meat, drinking the milk of tuberculous mals, or breathing impure air. Mr. Oldfield read a per in which, having regard to the danger of tuber- osis, he urged vegetarianism, but his views did not meet h much favor. A resolution was passed recommend- the abolition of ordinary slaughter-houses in towns of re than twenty thousand inhabitants and the substitu- n of public abattoirs. It was also resolved that the ecution of the Vaccination Acts ought to be transferred m the guardians to the sanitary authorities, with medical cers of health as their agents. Among other commu- nations to this and other sections were papers on "The rtality of Children in Dublin" (by Sir Charles Cam- n), "The Disposal of the Dead" (by the Rev. F. Lau- ce), "The Physicial Condition of Children" (by Dr. War-), and several on the disposal and treatment of sewage.

The latest intelligence as to cholera is favorable, there ng, according to information received at the offices of th Local Government Board up to last evening, no case a present in the United Kingdom. Further pressure is ng put on the Government from various quarters to p a stop to the immigration of destitute aliens. The dical officers of all ports are still exercising the utmost vdance. The latest returns show that the disease is dining in Hamburg, but stationary in Paris.

A renewed discussion has lately taken place in the pss on the sanitation of dwelling-houses—stimulated, dubtless, in no small degree, by the alarming intelligence o he near approach of cholera. Nearly everyone agrees th t some reform is needed, and that an intending tenant sl uld be able to obtain better guarantees that a house is n a sanitary condition than are at present generally o ainable. One suggestion is that further legislation should be sought to compel landlords to put their houses in sanitary order; another is that sanitary authorities should be persuaded to use more thoroughly the powers which they already possess. A useful proposal, and one which has already borne fruit, is that a voluntary system of registration of dwelling-houses should be adopted. So far this has only been carried out at certain health-resorts where visitors form a large proportion of the community, and lodging-house keepers are naturally desirous of doing all they can to attract them. If such a system, however, can be popularized in all health-resorts, there are hopes that it may be taken up more generally in time, and perhaps ultimately be universally adopted.

The death is announced of the well-known surgeon, Mr. Edward Cock, at the advanced age of eighty-seven. He was a nephew of Sir Astley Cooper, and received his professional education at Guy's Hospital. He subsequently became a member of the surgical staff, retiring as consulting surgeon in 1871. He was, perhaps, hardly known to the present generation, but in his prime he had no inconsiderable repute as a surgeon, and especially as an authority on the diseases of the male generative organs.

THE HEALTH-RESORTS OF THE RIVIERA.

(Continued from p. 327.)

XI.—MENTONE.

(From Our Special Commissioner.)

MENTONE AS A REAL HEALTH-RESORT—SITUATION AND ACCESSIBILITY—THE SHELTERING MOUNTAIN GIRDLE—METEOROLOGICAL OBSERVATIONS AND CLIMATIC PECULIARITIES—HUMIDITY—PARADISE LOST AND REGAINED—THE ROCHERS ROUGES AND THE BONE-CAVE—OVER-BUILDING AND HYGIENE—AN UNSATISFACTORY WATER-SUPPLY—DRAINAGE PROBLEMS—HEALTH OF THE NATIVE POPULATION AND PREVAILING DISEASES—PROFESSOR PROUST'S REPORT, AND THE PROPHYLAXIS OF CONTAGIOUS DISEASES—A MONUMENT TO DR. BENNET—SOME MEDICAL OPINIONS ON MENTONE—COST OF LIVING AT MENTONE—OUT DOOR LIFE AND AMUSEMENTS.

GENOA, April, 1892.

EVER since Dr. Bennet discovered, described, and developed this place for Anglo-Saxon people, Mentone has maintained its reputation as a real health-resort. It is certainly not, like Nice, a town of winter pleasures for people of leisure, and those human moths who ever swarm where sweetness and light abound; it is not, like Cannes, a lovely garden city, peopled by wealthy villa-owners; it is not, like Hyères, a staid and simple town, with a dwindling winter colony of aged cronies and conservative British stand-bies. No, Mentone is an old Italian village, gobbled up by France in 1860, on which English enterprise and discernment have grafted a prosperous winter sanitarium for sedate and sober-minded invalids.

From my personal observations I am inclined to believe that the average foreigner goes to Nice to have a good time. And if he gets sick there, he promptly decamps. He goes to Cannes because he can afford to maintain a costly and luxurious winter home in sunny Provence. He goes to Hyères because he is British and most of his great-grandparents went there before him, and latterly because the Queen has lived there. He goes to Monte Carlo to gamble, shoot at pigeons, and improve his morals. But the average *habitué* of Mentone goes there because he is sick and wants to get better, and because his doctor said so too. For doctors do not now send their patients to Nice, because they fear its treacherous attractions. Nor do they send them to Cannes, because they too rarely have the chance to do so. They don't send them to Hyères either, because only the dead doctors know about that place. And they certainly don't send them to Monte Carlo, because they would like to have their little accounts settled on the patient's return, and pilgrims home again from there never pay. So that, if the doctors really want to send sick people to the

French Riviera, they all advise Mentone. The result is apparent in the large proportion of wan and tottering wrecks that gasp along the promenade, and eject copious cultures of all the approved bacilli into as fair a landscape as you could wish to see.

It is necessary to reckon with this factor of the presence at Mentone of so many invalids, in weighing the advantages of competing health resorts. For it is no secret that some patients find the company of sick people so depressing as to neutralize the benefits that would otherwise accrue to them from a sojourn at a given place. It happens frequently enough, therefore, that patients will take leave of Mentone on their own responsibility, merely to avoid the daily meeting of so many fellow-sufferers. Nevertheless, as Mr. E. A. R. Ball[1] puts it, Mentone is *not* the town of which an Irish visitor is said to have remarked, that "but for an occasional funeral there would be no life in the place!"

Mentone, or in French *Menton*, is charmingly situated along a pretty crescentic bay, extending from Cap Martin on the west to Mortola Point on the east, a distance of some six miles if we follow the sinuous coast-line, and of four miles in a straight direction. The old town is closely built, on a small elevated promontory rising perhaps 130 feet above the level of the sea, and dividing the bay into two halves, known as the *Baie de l'Est* (East Bay) and the *Baie de l'Ouest* (West Bay). The East Bay has recently received the well-merited recognition of a separate railway station. This popular quarter is called Garavan. A cottage is found there with the following characteristic inscriptions: *Quartier de Gare-au-vent.—Le soleil, le climat doux et salubre, et l'eau de mer réunis constituent les principaux remèdes créés par le bon Dieu.—Louange à la gloire du bienfaiteur suprême qui a daigné nous en favoriser.—Première villa construite à Menton, pour y attirer les étrangers. par J. B. Franciosy*, 1855.

Mentone is only fifteen minutes by train in an easterly direction from Monte Carlo, and nineteen miles from Nice. It is less than seven miles westward from the Italian frontier station of Ventimiglia, and only ten miles from Bordighera. The place can now be reached by express from Paris in twenty-two hours.

The strangers' quarters are found only in the new town, which extends both to the east and to the west of the old one. It almost hugs the shore, and runs along for a distance of over three miles. Some hotels and villas have also been built more inland, and the town with its outskirts has begun to encroach on the hill-sides. But in the more sheltered eastern part little headway can be made in that direction, as the nearer mountains are too steep and too close to the shore. The whole town is well protected by mountain ramparts, which, when viewed from the sea or from an elevation, resemble an amphitheatre, with an opening southward facing the Mediterranean.

A number of mountain streams, which sometimes assume river-like proportions, run through the Mentonian territory. The Carsi, Borrigo, and the Gorbio, empty into the West Bay, and one torrent coming down from the *Val de Menton* is conducted into a main drain, which flows into the sea near the breakwater. The ravines through which these currents wind their way also constitute so many channels for cold atmospheric currents. Invalids will do well to avoid them, except on days of perfect calm.

Mentone has long enjoyed the reputation of being the warmest and most sheltered resort on the Rivieras. It has also been credited with having the most equable climate. As I will show, later on, these statements require certain modifications. The mountainous semicircle that rises up behind the town is, without doubt, an effective barrier to the cold winds from the north, and to a less extent to those from the east and the west. But chilly winds are felt at Mentone just as elsewhere on the Riviera, in spite of the contrary assertions of partisans.

[1] Mediterranean Winter Resorts. London: L. U. Gill, 1888.

Here is an extract from Mr. Brown's "Wintering a Mentone:" "With all its vaunted security from biting winds, and its mountain shelter from the northern blasts Mentone lies most invitingly open to the south, south east, and southwest, and winter winds from these directions can be chilly enough at times. What tells so keenly upon the weak and susceptible is the land breeze, which regularly at sundown steals upon the mountains toward the sea." In view of such truthful accounts, and always remembering the deep ravines intersecting some of the hills, it would seem that to describe Mentone as only exposed to "the sweet influences of the balmy south"[1] is more poetical than accurate.

The rugged outline of the rocky mountain peaks that form so beautiful a background to Mentone has frequently elicited words of admiration from pleased beholders. Indeed this semicircle of bold, bare heights is one of the conspicuous scenic attractions of the French Riviera. The mountain summits attain a height of from 3,000 to 4,500 feet. The highest peaks are named Mount St. Agnes. the Berceau, the Roc d'Ormea, and the Grammont. The climatic importance of these mountains seems sufficient to warrant the following description, borrowed from Sparks:[2]

"The posterior and lateral boundaries of the Mentone district are formed by a rough semicircle of limestone mountains, the highest peaks of which exceed 4,000 feet. The eastern wall rises almost abruptly from the sea, between Cap Mortola and the Italian frontier, at the gorge of the Pont St. Louis, and runs in a north-northwesterly direction till it culminates in the double peak of the Berceau (3.575 feet) and of the Grand-Mont, or Grammont (4,478 feet). The mountains now take a westerly direction, and between the two peaks of the Rasel (4,095 feet) and the Cime d'Ours (3,932 feet) leave a gap or pass by which the carriage road from Mentone to the Col di Tenda and Turin descends into the plain of Sospello. This pass, which is the lowest point of the amphitheatre of mountains which guards Mentone, is 2,574 feet above the sea. From the Cime d'Ours, a continuous chain (the highest peaks of which are the Aiguille or Mont Baudon (4,192), north of Mentone, and the Agel (3,695 feet), about five miles and a half west of the town), bends gradually round through west to south, until it terminates in the bold headland of the Tête du Chien (1,761 feet) above Monaco. A spur sent down from the Agel to Cap Martin forms the western geographical boundary of the Mentone district. Except at its eastern and western extremities the main bulk of the limestone wall does not come nearer the Mentone coast than three miles. The lower hills or ridges, which run from the mounts nearly to the sea, and at almost right angles to the shore, though in most cases originating in underlying spurs of the limestone, consist almost entirely of a more or less compact sandstone, evidently an old sea-bottom which has been upraised. These hills, to which Mentone largely owes the variety of its scenery and of its excursions, attain a height of from 400 to 700 feet." So much for Sparks.

Back of all these mountains still higher ranges rise successively until the main chain of the Maritime Alps, with peaks 9,000 feet high, is reached. And far inland we come finally upon the true Alps of Savoy and Dauphiny. I have purposely been thus explicit, for robbed of its mountain girdle Mentone could not exist as a winter health-resort.

As Mentone is really frequented by many invalids, it will not be out of place to indicate in what manner its meteorology and climate are peculiar. Now those who have endeavored to show that it is a health-resort absolutely *sui generis*, have erred on the side of excessive zeal. And yet it would hardly do to dismiss the subject by merely saying that Mentone enjoys a Riviera climate; for there is no doubt that appreciable differences exist

[1] The Riviera, by H. Macmillan, p. 161. London: J. S. Virtue & Co., 1892.

[2] The Riviera. London: J. & A. Churchill, 1879. p. 256.

between what may be reasonably expected at the East Bay and what ought to be looked for at the West Bay. Indeed the uniform experience of competent physicians shows that the therapeutic effects are not identical at these two places, separated though they be by a very short distance. But I shall return to this point later on.

The following table (borrowed from Sparks, but slightly modified) will convey as much information as it is possible for figures of that kind to convey. In regard to the authorities named, it should be mentioned that Andrews and Freeman may be set down as West Bay observers, while the records of Farina and Castillon refer to the East Bay.

TABLE OF METEOROLOGICAL OBSERVATIONS AT MENTONE.

Authority.	October.	November.	December.	January.	February.	March.	April.	May.
Freeman: Mean temperature	62.2	57.2	51.7	49.2	50.3	51.5	58.6	63.1
Farina and Castillon: Mean temperature	65.3	55.3	50.5	49.9	50.6	53.9	58.7	65.7
Andrews: Mean maxima	. . .	61.9	58.0	57.5	57.4	59.4	65.2	.....
Andrews: Mean minima	.....	46.4	41.5	40.6	39.7	42.0	48.0	.....
Freeman: Mean daily range	10.7	9.9	10.5	10.5	11.4	11.8	12.5	.....
Freeman: Barometer	29.84	29.91	30.06	30.03	29.86	29.71	30.01	.....
Freeman: Relative humidity	72	75	72	72	70	74	74	.....
Freeman and Andrews: Rainfall	6.37	3.73	3.47	1.24	1 45	3.69	3.29	2.37
De Bréa: Rainy days	9.0	9.4	5.9	7.9	5.5	6.1	7. 3	9.3
De Bréa: Very fine days	16.1	15.4	19.5	17.3	16.3	17.7	15.3	15.4
Stiege: Calm days	.....	22	23	19	20	18	.....	.....
Stiege: Windy days	.....	8	8	12	8	13	.....	.....

In addition to the information contained in the above table, it may be remembered that, as elsewhere on the Riviera, the months having the greatest number of rainy days do not necessarily correspond to those having the largest amount of actual rainfall. A glance at the following record clearly shows this. The table is found in the work of Sparks. (Gradation from left to right.)

	Highest.							Lowest.
Rainfall	Oct.	Nov.	Mar.	Dec.	Apr.	May.	Feb.	Jan.
Rainy days	May.	Nov.	Mar.	Apr.	Oct.	Dec.	Feb.	Jan.

As the Riviera climate is noted for its great dryness, it seems rather surprising to find the range of humidity set down as so wide for Mentone. Stiege has found it as high as 96 in December, and again as low as 16 in December and January. He also gives 83 as the mean for one season, and 68 for that immediately following. Sparks's lowest figure only descends to 35. From 70 to 75 will probably represent a fair average, although no two seasons appear to be alike. Other Riviera resorts are better off than Mentone in this respect, provided, of course, that an equable dryness is a therapeutic desideratum for the patient in question.

The Mentonese have a modest little tradition concerning their lemons, which are really exceptionally fine and are exported to distant cities, where they always command high prices. This is the tale as told at Mentone:[1] When the pair of original sinners were driven from Paradise, mother Eve managed to snatch a luscious lemon which she secreted somewhere about her person. (A clever trick.) She decided to bestow it upon the country that should most remind her of her late home. In the course of her weary wanderings she came at length to a site so filled with light and rich in fragrance, that she verily believed to have once more returned to Paradise. Hesitating then no longer, Eve gave up her lemon, saying: "Behold! this coast is worthy of you!" Now, the spot where this occurred is where Mentone's lemon groves still yield many millions of the same fruit that once grew in Paradise.—*Si non è vero, è ben trovato*

[1] De Marseille à Menton, par Jules Adenis, p. 360. Paris: A. Hennuyer, 1892.

At the East Bay are found the famous *Rochers Rouges* and the celebrated bone-caverns which have puzzled even real geologists, let alone mere medical beholders. Mr. Hare alludes to the red rocks and caves as follows: "A rugged path beneath the cliff leads round the rochers rouges to a platform whence there is a splendid view of the town and of the mountains, embracing the distant coast of France, the Esterels and Antibes with Monaco, Mont Agel, Turbia, Monts Garillon, Baudon, St. Agnes, and the Berceau. The red rocks themselves are exceedingly fine, both in form and color. They are overgrown with rue, rosemary, and euphorbia. In their caverns a great number of bones of the stag, goat, horse, wild boar, wolf, wild-cat, and rabbit, have been discovered, with an immense quantity of shells of the still existing kinds of fishes. These, and the number of fragments of rude weapons in flint also discovered here, led to the supposition that these caverns must once have been inhabited by Troglodytes as described by Strabo and Pliny."

Only a short distance from the red rocks is the wildly picturesque gorge of St. Louis, spanned by a bold bridge of but a single wide arch. Half-way across the bridge you first touch Italy. Under this bridge the remains of an old aqueduct are seen to this day. "The rocks, towering precipitously above on either side, are remarkably bold and rugged, while the eye looks from the white arid heights, bleached by the fierce glare of the sun, down over the parapets into the cold, dark chasm, with a shiver. This weird ravine now marks the appropriate and well-defined boundary between France and Italy. The Italian douaniers have their station-house by the road-side, a little beyond the bridge, perched prominently on the highest part of the precipitous rocks." (Macmillan.) The French custom-house is situated nearer Mentone. And from all appearances smuggling does not flourish in the immediate neighborhood.

Taken as a whole, the French Riviera is now decidedly overbuilt, as empty villas and apartments, complaining landlords, and a perceptible tendency to rather lower rents sufficiently attest. This feature is particularly noticeable at Cannes and Nice. But Mentone also shows it. Speculative booms have been more or less successfully engineered at all these places. The receding wave of prosperity may teach the "promoters" a useful lesson. From a strictly sanitary point of view, safety for the Riviera resorts lies in keeping the individual towns small. But with anything like a spasmodic growth, drainage and other difficulties always threaten to overwhelm the towns, the authorities being unable apparently to appreciate the bearing of suddenly enlarged demands. The officials are without doubt honest enough, and they all have benevolent intentions. But modern sanitary science is to most of them a book sealed with seven seals.

I was gravely assured on one occasion that a particular kind of suspected Riviera water was perfectly pure, for the Mayor himself had a bottle sent to his office every morning, which, after vigorous shaking, was duly held up to the light, smelled, tasted, and then invariably pronounced perfectly pure and potable. Very likely when the Mayor has a cold in the head the President of the Council performs by deputy, the daily smelling test. The simplicity of this olfactory method would seem to recommend it to a more extended sphere of employment.

Apart from inevitable drainage difficulties which arise when villages are transformed into towns, another drawback of overbuilding consists in the fact that the hastily erected modern dwellings do not fulfil the just requirements of invalids. They cater too much to the *insouciance* of the tourist or the love of show of the *rentier*.

A French physician, Dr. Alméras, in a report made to the Medical Society of Mentone, has observed that fewer patients now visit the littoral than was formerly the case. The Carnival festivities still attract heterogeneous and ephemeral crowds, and many tourists with circular tickets make a brief stay there. But those invalids who formerly enriched the Mentonese by repeated long sojourns are diminishing in numbers.

Of course Egypt is just now a decided competitor of the Riviera as a winter home for lovers of sunshine and warmth; yet I have no doubt that more attention to sanitary details and matters of public hygiene would greatly enhance the value of this coast to the sick. What is sauce for a pleasure resort is not always sauce for a climatic health station.

In the words of Dr. Onimus: "*Nulle part les questions d'hygiène public ne sont aussi importantes que sur le littoral; elles sont la base de la fortune des habitants, et la négligence de leur mise en pratique peut entraîner des conséquences désastreuses.*"[1]

Mentone is not very abundantly supplied with drinking-water by a company controlling a branch of the Nice Canal de la Vésubie. It is the same kind of unsatisfactory water as is conveyed in an open canal to Monte Carlo. The natives appear to take it without detriment to their health, in spite of its inevitable organic impurities, and the large proportion of lime compounds which it contains. There is no doubt that many strangers have also used this water without knowledge of the risks thus blindly taken. The water is collected in large reservoirs before final distribution. Filters are in common use, but I am sure they are mere delusions and snares so far as any real protection from possible infection is concerned. Boiling is the sole safeguard that will make the Mentone water potable. I append an

Analysis of Mentone Drinking-Water.[2]

Water Clear and Without Odor. One Litre of Water Contains:

	Grammes.
Organic substances and volatile products	0.074
Dry residue	0.397
Organic matter (permang. in acid liquid)	0.0014
Organic matter (permang. in alkaline liquid)	0.0005
Carbonate of lime	0.105
Sulphate of lime	0.280
Alumina	traces
Magnesia (sulph. carbonate)	0.002
Silica and insoluble earthy compounds	0.007
Chloride of sodium	0.0058
Nitrates	0.001
Nitrites	0.00
Ammonia	0.00
Albuminoid ammonia	slight traces

The town of Mentone possesses a number of large-calibre main drains, with collateral branches running through most of the streets, the whole net-work of sewers discharging by several outlets into the sea and harbor at no great distance from the shore. The authorities entertain the utterly mistaken notion that their former drainage problems have been satisfactorily settled by the establishment of these channels, which were completed over ten years ago. But it may be questioned whether Mentone was not better off in the old days than with a drainage system which fails to drain, and which extends to noxious gases a permanent invitation to enter apartments from which they were formerly excluded.

In the little country settlements of Southern Europe all house-slops and excreta are scrupulously preserved in closed caskets or bins, which are carried to such places as call for a fertilizer. Those who have no personal use for such substances sell them to the peasants who have.

In Provence and Liguria this system has worked well enough in the purely agricultural districts. Mentone formerly employed this primitive method of refuse disposal without detriment to her health. But when the place became the resort of increasing numbers of Englis winter residents the natural demand for modern improv ments arose. At first cesspools were sunk into th ground. Then the authorities yielded to the pressu brought to bear upon them, and constructed drain These, however, were only intended to carry off surfac water and kitchen waste, but not house soil proper. Th old cesspools remained in use, or new and generally in perfect ones were established. As the new English cal inet arrangements, with their large flow of water, were ne introduced, the cesspools rapidly filled, and to prevei the expenditure of frequent pneumatic aspiration, ove flow conduits were made to connect with the street drain It is the same story which has been repeated in almo every particular in all the Riviera health-resorts. Excep at Cannes cut-off traps and adequate vent-pipes are sti all but unknown. Now Nice and Cannes are wide-awal and realize their needs, whereas Mentone is half aslee in reference to this vital matter, and may therefore fai much worse than some of her competing neighbors. Wit a plenteous water-supply and numerous flushing-tank such as are now found at Nice and Cannes, there woul be less danger in the existing Mentone arrangement But at the latter place they really have to rely on tl accident of rain to accomplish what should be regulate by absolutely reliable contrivances. The stenches whic at times arise from the culverts in the streets of Me tone, and at certain points along the shore, should wai normally sensitive nostrils that there is something rotte somewhere. But the natives seem positively to enjc smells that fill the uneducated newcomer with disgust.

It is high time that the Mentonese should descend fro their pedestal of lofty disregard for the sanitary requir ments of an ambitious health-resort, and buckle down t work of a practical and efficient kind, otherwise th may discover what it means to be left to stew in the own juice.

In this connection I may observe what I have alreac elsewhere alluded to, namely, that defective sewerage sy tems may be fraught with grave dangers of a potenti rather than actual kind. But is it prudent or necessa to await an actual outbreak before instituting radical r forms? I hope not.

In spite of living in cramped quarters, amid unhygien surroundings, the Mentonese continue to enjoy fa health. The foreigner is always more liable to suff than the native from time-honored evils. Typhoi fever has repeatedly occurred there, but fortunately it ha never assumed the proportions of a virulent epidemi The foreign colony, while not exempt, has not been vi lently attacked.

Through the kindness of the English Consul, M Charles Palmaro, and the exertions of Dr. Stanley Rer dall, as well as the courtesy of M. Louis Laurenti, th Mayor of Mentone, I am able to present the followin official table:

Table of Deaths at Mentone for the Past Five Year

Population (exclusive of foreign colony), 9,387.

Year.	Deaths.	Pro Mil
1887	212	22.
1888	183	19.
1889	189	20.
1890	214	22.
1891	199	21.
Total	997	106.

Average mortality for five years, 21.2

Taking the official record for an average good ye (*i.e.*, that of 1888) I select the following details as to tl

Causes of Death Among Natives at Mentone.

	Cas
Typhoid Fever	
Measles	
Scarlatina	
Diphtheria	
Phthisis[1]	

[1] L'Hiver dans les Alpes Maritimes, p. 119. Paris, 1891.

[2] Supplied through the courtesy of the Mayor, and in conformity with the analysis made by the Compagnie Generale des Eaux, November 17, 1891.

[1] Twenty-seven cases o death from phthisis are reported among t foreign colony for the same year. A marked contrast.

	Cases.
Tubercular affections other than phthisis	18
Pneumonia	24
Bronchitis	6
Gastro-intestinal affections	10
Unclassified	51

It is somewhat unfortunate that so large a proportion of deaths is found under the heading "Unclassified," but at any rate even close contact with the natives would not seem to entail any extraordinary danger on winter visitors. Nothing special is to be noted at Mentone with regard to prevalent maladies.

According to Sparks, facial neuralgia is very common; and I have no doubt that the sudden changes of temperature occurring on the Riviera invite attacks of neuralgia even in those not ordinarily subject thereto. Phthisis and tuberculosis appear to be more frequent now than formerly. But this should not surprise us, in consideration of the vast quantity of bacillary material carried into Mentone every winter by foreigners.

Scrofula is said to be on the wane at this resort, probably because the native population is now better fed than formerly. From the tables kindly supplied by the Mayor it would also seem that there are plenty of old people at Mentone.

Professor Proust, of Paris, the Inspector-General of the sanitary service for the state of France, has quite recently examined Mentone. The Mayor has kindly given me a copy of his report, and the following extracts from this important official document may prove instructive. I have retained the language of the original, because it reads almost like English.

RÉPUBLIQUE FRANÇAISE.

PRÉFECTURE DES ALPES-MARITIMES.

"*Extrait du Rapport de M. le Docteur Proust, Inspecteur Général des Services Sanitaires.*

VILLE DE MENTON.

". . . . Puis venant à parler de la mortalité constatée à Menton pendant l'année 1890, et de la disparition presque complète de la variole par suite des vaccinations et revaccinations pratiquées en masse, M. le Docteur Proust ajoute:

"Le corps médical de Menton et la municipalité se prêtent un mutuel et constant appui pour que la prophylaxie des maladies transmissibles soit assurée, et la population obéit docilement aux injonctions de l'administration; elle se félicite de son concours et ne manque pas de le rechercher chaque fois qu'elle en éprouve la nécessité. Cette ville a en effet compris, notamment depuis le tremblement de terre, que son relèvement si rapide et sa bonne renommée auprès des étrangers dépendaient en grande partie de sa salubrité.

"(Les sages dispositions arrêtées par le Syndicat des hôteliers de la ville pour la prophylaxie des maladies transmissibles sont reproduites in-extenso dans le rapport de M. l'Inspecteur Général, qui les fait suivre des réflexions ci-dessous):

". . . . On pourrait discuter assurément quelques-unes de ces dispositions; mais telles qu'elles sont, elles témoignent d'une initiative trop précieuse pour qu'il n'y ait pas lieu de les signaler à l'attention publique, et de féliciter le Syndicat des hôteliers de Menton de n'avoir pas hésité à pratiquer de lui-même, pour le plus grand profit de sa clientèle, tout un ensemble de prophylaxie pour lequel certaines sociétés scientifiques n'ont pas encore osé se mettre d'accord."

Mentone, as a flourishing health-resort, may be in itself regarded as the best and most eloquent monument that a foreign physician could ever hope for in France. Nevertheless, it is satisfactory to perceive that, at the beginning of this season, a subscription list was opened for the purpose of supplying funds for the erection of a suitable monument to the memory of him who did so much for his adopted home. The Mayor heads the list, and under his patronage it is believed that enough money can be raised to do suitable honor to Dr. Bennet's memory. People so often forget live doctors that they ought to be glad of an occasional opportunity to remember a dead one.

Having given my own impressions of Mentone, it seems advisable to record the opinions of other observers.

Now, most medical writers have expressed favorable views concerning the climatic advantages of Mentone. But on the equally important sanitary aspect of the place they are singularly silent. It is true Dr. Bennet has freely admitted the vital significance of sanitation, and, indeed, claims to have made hygienic conditions the chief basis of his researches. But the more recent authors have little to say on the subject, perhaps for the reason that much praise cannot be given to the Mentonese on the score of sanitary improvements.

According to Dr. Bennet:[1] "The exceptional warmth of the winter climate of Mentone, even for the Riviera, is proved, beyond all question or doubt, by the presence of groves of large, healthy lemon-trees, which ripen their fruit, without artificial protection, every year in the fullest perfection, in nearly all the ravines and on the warmer hill-sides." That "the vegetation of Mentone is that of the most favored portions of the Riviera" (Hassall) is quite true, but almost all these winter-stations have little nooks where a similar luxuriance is observed, and some of the valleys at San Remo are quite as well provided with flourishing lemon-trees as those of Mentone.

The same author (Bennet) sums up the characteristics of the climate of Mentone as follows: "Absence of frost, prevalence of northerly winds, moderate dryness of the atmosphere, complete absence of fog, paucity of rainy days, clearness and blueness of sky, general heat and brilliancy of sun, a cool night temperature, a bracing coolness of the air, and a mean difference of 12.8° F. only between the day maximum and the night minimum."

I believe this summary to be a fair statement of the real conditions in all but the last item. It is possible that an average of 13° may represent the difference between night and day. But the difference between sun and shade temperature is probably five times as great. And invalids are more concerned with the diurnal variations of sun and shade temperatures than with shade maxima for the day and nocturnal minima.

Writing in the *British Medical Journal*, February 9, 1884, Mr. Ernest Hart says of Mentone:

"Its groves of olives, its luxuriant lemon-trees, its palms, bananas, and carouba trees, testify to the absence of frosts; the clustering roses, the mimosas, laden with sprays of golden blossom, the primroses, daisies, and violets remind us of the beauties of our temperate zone.

"Of all the towns of the Riviera, Mentone is the most sheltered; its vegetation is the most perfect; its site, surroundings, and arrangements are most carefully adapted for the invalid. The healthy are learning from the experience of the sick. The pleasures of a winter holiday in the Riviera are known as yet only to a small minority of those who wearily plod through dull, foggy, and icy months of labor, rendered heavier by failing health and spirits, and half valueless by jaded and threadbare tediousness of unremitting toil in sunless surroundings."

This was written eight years ago. Mentone has changed but little since then, and the only exception I must take to Mr. Hart's eulogium is the statement relating to "arrangements most carefully adapted for the invalid." If Dr. Bennet's prudent counsels had been more largely heeded, if the needs of invalids had been always fully considered, Mentone would be by long odds the most desirable health-resort on the Riviera.

The climatic advantages of Mentone are summed up by Dr. Burney Yeo as follows: "Considered generally, the climate of Mentone may be taken as a favorable example of the Riviera climate; and it has the great advantage of possessing, as it were, two climates, suited to

[1] Winter and Spring on the Shores of the Mediterranean, pp. 14 and 81. London: J. & A. Churchill. 1875.

two different classes of invalids. For those who especially desire warmth and shelter, and a quiet, indolent life, with plenty of sunshine and sun heat, and who like to live close to the sea, there is the mild and sedative climate of the East Bay, with its southern exposure, and its almost complete protection from strong winds. For those, on the other hand, who find advantage from a more bracing air, who like to have the sun heat tempered by cooling winds, who cannot feel at ease without 'ample space, and room enough' to wander free over hill and valley, or who are irritated by the monotonous beat of the tideless sea against the shore—for those there is the West Bay, with hotels and villas, some on the seashore, some a little removed from it, some—and those the newest and best—far removed from the sea, and high up on the hill-side. The value of a climate of this kind in many forms of pulmonary affections, in certain chronic, gouty, and rheumatic conditions, in states of anæmia, in convalescence from many acute diseases, and in the many infirmities to which old age is exposed, is incontestable."

The East Bay being squeezed in, as it were, between a high mountain and the seashore, complaint has been made that the excessive warmth was enervating. Dr. Prosser James says: "Beneath its eastern cliff a warmer temperature is to be obtained, but only at the cost of exercise and fresh air. It is the depressing influence of this confined air which has made some authors attribute to Mentone a sedative influence"

Dr. C. T. Williams states: "The climate is warm, very dry, and stimulating; it is often very equable. There is a want of circulation in the atmosphere, particularly in the eastern bay, where, in addition, the close proximity of most of the houses to the sea subjects patients too much to the noise and stimulating effects of that element."

For my own part, I believe that Dr. Hassall has more clearly stated the case than either Dr. James or Dr. Williams. He writes,[1] that each of these bays possesses both advantages and disadvantages, the one being suitable for one class, and the other for a different class of cases. During the three colder winter months there is no reason to complain of the closeness of the atmosphere of the eastern bay, it is only early in the autumn and in the spring that it will be found at times too warm and close for some, and consequently somewhat debilitating. The climate of the western bay has been compared to that of San Remo, but the comparison is one which cannot be maintained. The mean annual temperature of San Remo is 60.13°F., the mean three months' winter, 48.89°F., that is to say only 0.09°F. less than the eastern bay, while the number of rainy days is but forty-five. Then, again, San Remo is protected on the west by a lofty headland 800 feet in height, and there are no breaks or gaps in the surrounding semicircle of mountains comparable to those made by the Carei and Borrigo valleys.

If you want to live well at Mentone you will have to pay for it. Hotel charges are a little less than at Cannes and Nice, but Mentone has long ago deserted the ranks of the cheap places. Lodgings are also slightly lower than at Cannes and Nice, but the cost of housekeeping appears to be about the same at all the leading Riviera resorts. The stores do not tempt you by the brilliant display of costly luxuries as at Nice, but all the essential needs are amply provided for by obliging shopkeepers. You are, of course, everywhere expected to pay the usual tribute of extra charges exacted of all foreigners, and pay without grumbling. This is only fair, in view of the fact that you are not openly taxed for sunshine, although rooms "*au midi*" are always much dearer than those having a northern exposure.

A daily open-air concert that would painfully jar on the tympanum of a lover of real music, a mild Carnival (including dainty *batailles des fleurs*) such as is befitting the serious character of a winter sanitarium, an energetic match-playing tennis club, some cycling, plenty of walking and driving along roads that are often insufferably dusty, the climbing of hills and mountains by paths of tortuous picturesqueness to points of varied beauty overlooking gorgeous panoramas, timid attempts at boating, an occasional eccentric hazard in a piscatorial direction, meek dances and weak teas—thus qualified in deference to an undue preponderance of seedy-looking curates—lots of hazy sketching and amateur color splashing on defenceless canvas, frequent contemplative baskings in fervid sunshine, a gathering of beautiful wild flowers, the devout admiration of lemons and oranges of unusual size, bountiful opportunities to work off poor French and poorer Italian on an indulgent populace, the daily record of wind and weather, the pitiless resolve to write a book about all this and expect one's friends to read it—this about comprises the catalogue of those sinful acts of existence which you are expected to engage in at Mentone.

Life there is modelled after the fashion of those who needs must husband strength and store up energy for future use, and not at all as at Nice, where it takes its cue from idle loungers intent on feverish sport and ever thirsting for new forms of dissipation. And knowing what awaits you at Mentone, the place will surely not disappoint you. But go there expecting to find what never had a home in that quarter, and you are foredoomed to regret your choice. A cultured mind in an enfeebled body, no matter what may be its precise pathology, will doubtless find a winter season spent there of congenial benefit. But a feeble mind in a merely untutored body needs other vantage-ground of a more boisterously joyful kind for leading a life satisfactory to its own specific requirements. For him who has overdrawn nature's store of health, Mentone offers a fair chance of re-establishing a reserve balance. But if you are still blessed with a handsome surplus of bodily vigor, do not attempt to play the prodigal in this quiet, serious, sunny town on the shores of a smiling ocean.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 8, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	44	6
Scarlet fever	52	4
Cerebro-spinal meningitis	1	5
Measles	31	2
Diphtheria	58	21
Small-pox	6	1
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Students at the Universities of Paris, Vienna, and Berlin number, respectively, 9,215, 6,220, and 5,527. In contrast with these there is a college in Sierra Leone which boasts of but twelve students and five professors. The total number of universities in the world, according to the *Minerve*, of Strassburg, is one hundred and forty-seven.

A Woman's Dental College in Sweden.—Miss Elena Lewin, a recent graduate of a dental college in Gothenburg, has obtained permission from the authorities to establish a school of dentistry for women in Sweden, and is now organizing the school and hopes to open it in Stockholm this autumn.

MOVABLE KIDNEY AND DISEASES OF THE GENERATIVE ORGANS IN THE FEMALE.[1]

By J. SCHMITT, M.D.,

NEW YORK.

In a lecture delivered some time ago on the subject of movable kidney, a physician of repute found fault with a colleague who removed the ovaries in a patient afflicted with this disease. Her ovaries were sacrificed, but the movable kidney, with its tormenting symptoms, remained as before.

In reflecting upon this subject we meet with so many interesting points, that I thought it worth while to present them in a connected and condensed form.

If we examine all women for displacement of the kidney, we are surprised at the frequency of the disease. I do not exaggerate when I maintain that at least one woman in ten is afflicted with a more or less advanced displacement, usually of the right kidney. We must, of course, spare neither time nor pains which a thorough examination of the kidney requires.

Under favorable circumstances the lower end of a normal kidney can be palpated.

For this purpose it is best to examine bimanually. The patient lies on her back, or on the sound side, with hips and knees well bent. On pressing one hand beneath the free border of the ribs, and making counter-pressure with the other hand over the region of the kidney posteriorly, letting the patient at the same time take a deep inspiration, the lower end of a normal kidney can usually be felt, provided the abdominal walls are thin, the intestines empty, and contractions of the abdominal muscles do not occur. The first stages, which consist in a simple loosening of the kidney, can easily be detected by this method. During inspiration the kidney slips downward, and if held at the height of inspiration, can be prevented from slipping back during expiration.

All degrees of displacement may occur, from a simple loosening of the kidney to its lodgement in the pelvis.[2] It generally descends behind the peritoneum between the layers of the mesocolon, sometimes more internally, projecting beneath the free border of the ribs; sometimes more externally, expanding the outer layer of the mesocolon.

As a rule, the intestine lies between the abdominal wall and a movable kidney; but with sufficient laxity of the peritoneum it may lie in direct contact with the anterior abdominal wall. In well-advanced cases we find the kidney either in the iliac fossa, or at the pelvic brim, to the side of the promontory.

Generally we are justified in pronouncing an oval, solid, easily movable tumor, which is tender on pressure, and situated in the lateral abdominal region, a movable kidney. Occasionally we are surprised at the varying results obtained by the examination. The first examination reveals a movable kidney beyond doubt; at a later examination we are unable to detect it. In these cases it is advisable to let the patient cough, or examine her in a sitting or standing posture.

I take the liberty of presenting two patients in whom the abnormal mobility of the right kidney can easily be determined by the above method of examination. In the one case the right ovary was removed for the relief of nervous disorders, but the presence of a movable kidney was overlooked. With the same right we might have extirpated the movable kidney, and allowed the ovary to remain; for the symptoms of a movable kidney are very similar to those caused by certain sexual disorders.

Patients with a movable kidney have a disagreeable feeling of weight and pressure in the abdomen—a feeling of dragging, as if a weight in the abdominal cavity were settling downward. They complain of pains in the hypochondriac and lumbar regions, which may radiate upward to the shoulder, or downward to the pelvis and thigh, ordinarily corresponding to the side of the displacement. Traction and pressure on the peritoneum and nerves in the vicinity of the displaced kidney give rise to manifold nervous disturbances, viz., peritoneal irritation, neuralgias, reflex phenomena, etc.

Bodily exertions aggravate, rest and lying on the back relieve, the symptoms. Such patients feel best on rising in the morning; walking about and attending to their usual occupations bring back their suffering. After the disease has existed for some time, rest in bed no longer procures the desired relief. Digestive disturbances are very common. They vary from a feeling of oppression, nausea, vomiting, to the most violent cardialgias. Gradually the whole complex of hysterical symptoms, and even mental derangements, may be developed.

It is not my intention to give an exhaustive record of all the symptoms dependent upon movable kidney. I refer only to such as are identical with symptoms produced by certain sexual disorders. The movable kidney puts the power of resistance of the nervous system to a test of as great an extent as do certain uterine and ovarian diseases. Women suffering from nervous debility—be it inherited or caused by faulty education, chronic diseases, or sorrows—are most seriously influenced.

In certain individuals a movable kidney produces no symptoms whatever. In others they may be limited to a single disturbance; while in still others it may give rise to the entire series of hysterical symptoms. We have this same experience in sexual disorders; the same disease which hardly annoys one patient may bodily and mentally incapacitate another.

The relations of movable kidney and the sexual organs may be considered from different points of view; the one dealing with a similarity of symptoms, I have just considered.

For the sake of completeness, though not within the scope of my paper, I would like to explain briefly to what extent a movable kidney, pregnancy, parturition, and menstruation may influence each other.

A movable kidney, located in the pelvis, has occasionally been discovered during pregnancy or during parturition. As far as I know, it has never interfered with the regular course of pregnancy or labor.

Movable kidneys sometimes become attached by an adhesive peritonitis, and if fixed in the pelvis may lead to errors in diagnosis, which are usually cleared up after laparotomy. An acquired movable kidney can generally be pushed upward from the pelvic cavity, whereas a

[1] Read before the Section on Obstetrics and Gynecology at the New York Academy of Medicine, February 25, 1892.

[2] Some writers distinguish between movable and floating kidney, and assign to the latter a proper mesonephron. This can, of course, only be demonstrated at the autopsy, and even then it might be difficult to determine what is congenital and what acquired. Clinically such a distinction is not appropriate, as the symptoms do not differ, and a movable kidney may become floating.

congenital one is immovable. The former preserve their shape more distinctly, while in the congenital cases changes in form and anomalies in the origin of the blood-vessels are not infrequent. (Orth.)

The discomfort of movable kidney is ordinarily relieved during pregnancy; the growing uterus pushing the kidney upward forms a natural support. There are, however, exceptions to this rule. I observed a patient who occasionally had severe attacks of pain on the side of the movable kidney even in the latter months of pregnancy. During the puerperal state the symptoms may return, even before the patient has left the bed. At least I have seen the return of the nervous and dyspeptic ailments of a right-sided movable kidney in childbed. In all probability the abdominal pressure during labor causes a return of the displacement of the kidney with its symptoms.

But little remains to be said concerning the influence of normal or normally acting sexual organs on a movable kidney. Some physicians maintain that a congestion of the kidney occurs at each menstrual epoch. This gradually leads to a relaxation and loosening of the organ, and finally to a sinking of the kidney. This, of course, is merely an hypothesis, which you can accept or reject as you choose. It is a fact, however, that the symptoms of movable kidney occasionally become aggravated during menstruation.

Though the relations of movable kidney to the normal sexual organs, which I have just described, be of subordinate importance, the relations to diseased sexual organs prove to be by far more interesting.

Certain of the genital diseases bear no relation whatever to a displaced kidney; they coexist only accidentally. I, at least, cannot detect any relation that a gonorrhœa or a pyosalpingitis might have to a movable kidney. On the other hand, however, a number of sexual disorders frequently occur in connection with a movable kidney; so that we are justified in assuming a mutual dependence and a common etiology. To this class belong retroflexion, prolapse of the uterus, cystocele, retrocele, and chronic inflammations of the uterus and ovaries. In order to make the relations of these diseases to movable kidney intelligible, I request you to recall to memory the etiology of movable kidney.

Many physicians ascribe tight lacing, which indirectly, by pressure on the liver, forces the kidney out of its position, as the chief factor in the causation of movable kidney on the right side. Others lay more stress upon the loss of fat from the adipose capsule of the kidney, which connects it to the adjacent tissues. Should the fat disappear as the result of wasting disease, then a loosening and sinking of the kidney take place. Continued coughing, straining in chronic constipation, in general all conditions which frequently and persistently maintain the diaphragm in an inspiratory position, are liable to produce a displacement of the kidney. Congenital conditions, abnormity in the attachment of the kidney, play an important part in so far that they predispose these individuals to acquire a movable kidney.

From the above it follows that the causes which lead to movable kidney are not the same, and must be determined in each particular case. On one point, however, a striking harmony seems to exist, namely, that women in whom the elasticity of the abdominal walls has been diminished, either by pregnancies, tumors, laparotomies, or wasting diseases, suffer comparatively frequently from a movable kidney. The relation of movable kidney to laxity of the abdominal walls can easily be understood by recalling the physiological action of the abdominal walls.

The abdominal contents are inclosed by elastic walls: the diaphragm with the lungs, the lower portion of the thorax, the abdominal parietes, and the floor of the pelvis. The pressure exerted by these walls on the abdominal contents, and especially on the elastic intestines, including the stomach, produces a tension within the abdominal cavity which is properly designated intra-abdominal pressure. In its production the abdominal walls are an important factor. Like an elastic band they encircle the abdominal contents, and owing to their contractility and expansibility accommodate themselves to the physiological and pathological changes in volume of the abdominal cavity. They keep the abdominal contents in apposition, and exert a pressure which, in addition to the anatomical attachments, offers an essential support in maintaining the relative position of the abdominal and pelvic organs.

Should the abdominal walls for any reason become insufficient, then a lowering of the intra-abdominal pressure results. With this a series of disturbances take place in the abdominal cavity, relating principally to the position of the abdominal and pelvic organs and the circulation. The changes consist in a sinking of the intestines, the liver, and the kidneys, and a flattening of the diaphragm. It has even been asserted by some that dilatation of the stomach and displacement of the transverse colon to the lower part of the abdominal cavity are caused by laxity of the abdominal walls, or its equivalent, a lowering of the intra-abdominal pressure.

The position of the uterus does not depend to so great an extent on the intra-abdominal pressure, although this is evenly distributed in the abdominal and pelvic cavities. Other causes must be added to produce a displacement. As a matter of fact we frequently find metritis and laceration of the pelvic floor with laxity of the abdominal walls.

Chronic inflammation of the uterus, endometritis, metro- and menorrhagia, may easily be caused by insufficient action of the abdominal walls. As the activity of the muscles is necessary for the production of an energetic blood- and lymph-current in the limbs, so the respiratory fluctuations give an impulse to the circulation which can only be efficiently maintained when the physiological pressure in the abdominal cavity remains normal. Should this be diminished, then hyperæmia of the venous system with its consequences can easily set in.

Another series of symptoms still remain which can be traced to the same cause—the lowering of the intra-abdominal pressure consequent upon laxity of the abdominal walls. To this category belong chronic constipation, disturbances of digestion, and pains due to traction upon the peritoneum and the nerves. Hegar attributes the lumbar pains to straining of the extensors of the vertebral column. Women with insufficient abdominal walls bring the lumbar vertebræ into lordosis, and their pelvis to a more marked inclination, in order to throw the centre of gravity further forward.

From these explanations it will be apparent why some authors do not consider movable kidney as a distinct disease, but merely as a symptom of diminished intra-abdominal pressure. The abdominal contents are partially deprived of their support, and more strain than usual is put on the anatomical attachments. Traction on the mesentery and the peritoneum—so they claim—produces disturbances of the stomach, the intestines, the nerves, the blood-vessels, etc. This view is undoubtedly correct for many cases in which a pronounced laxity of the abdominal walls is present, *i.e.*, thin, folded walls with but little contractile power, diastasis of the recti, etc. It will not hold good, however, in those cases, not infrequently met with, in which the power of the abdominal muscles is unimpaired.

Thus far I have said nothing of the part taken by the perineum in the production of intra-abdominal pressure. Its action is similar to that of the abdominal walls. It forms the elastic boundary of the pelvis below and posteriorly, and participates in the respiratory movements; it bulges during inspiration and flattens in expiration. Its influence in the production of the intra-abdominal pressure is not of as great importance as that of the abdominal walls, since the elasticity of the perineum acts at an angle on the abdominal contents indirectly through the zigzag formation of the uterus and vagina.

Laceration of the perineum, when trifling, is not necessarily followed by a decrease in the intra-abdominal pressure, because the uterus, vagina, and remainder of the perineum can offer a sufficient amount of elastic resistance. Should these, however, prove insufficient, then a lowering of the intra-abdominal pressure necessarily follows. This is greatest in the pelvic cavity, and the detrimental results will especially affect the pelvic organs; the more so if a normal, or but slightly diminished, pressure is produced in the abdominal cavity above. This pressure acts in all directions, and in the pelvis, the place of diminished resistance, will give rise to displacements of the pelvic organs—descensus uteri, cystocele, and rectocele.

Whether relaxation and laceration of the perineum alone are sufficient to produce a relaxation of the intestine and sinking of the kidney, I do not venture to say. They undoubtedly, however, predispose to the displacement, especially when combined with insufficient abdominal walls.

The circulatory disturbances in the pelvis are analogous. The venous congestion of the pelvic organs becomes the more marked the greater the difference between the abdominal and vaginal pressure; a condition that can easily be established in cases of insufficiency of the perineum with proportionately normal abdominal muscles. At all events there is nothing forced in the conclusion that the coincidence of movable kidney and chronic inflammation of the pelvic organs is not merely accidental, but due to common causes. That the relations must not always be as stated, but that local conditions may occasionally be the principal causes, need hardly be added.

I must not, however, omit the view, that displacement of the pelvic organs may produce displacement of the kidney by traction on the uterus.

The disturbances in the excretion of the urine remain to be considered. Pelvic exudations, tumors, and retroversion of the uterus, may, by compression or torsion of the ureter, lead to obstruction of the urine with its consequences. The hydronephrosis and inflammatory changes of the kidney thus produced give rise to increased weight and a sinking of the organ. On the other hand, obstruction to the urine not infrequently occurs in movable kidney independent of sexual diseases. It is produced by twisting of the ureter, and gives rise to acute hydronephrosis, severe colics, fever, vomiting, etc.

Notwithstanding the frequency of sexual diseases and movable kidney, one thing appears striking, namely, that we are seldom in a position to observe at the bedside the characteristic results of the occlusion of one or both ureters, viz., diminution of the excretion, hæmaturia, temporary albuminuria, and nephritic colic. In all probability, the symptoms of the first stages of hydronephrosis are overlooked, or they are so slight that even the patient does not pay any attention to them. In the majority of cases the obstruction to the passage of urine is overcome by the force of the renal excretion, without causing intense colics or a palpable transitory renal tumor.

Concerning the treatment, it is obvious that he will be most successful who takes both diseases into consideration. Whoever directs his treatment for lumbar pains, dyspeptic and nervous disorders, exclusively to the sexual organs, without paying any attention to a movable kidney, must not be surprised at a partial or complete failure. And he who attempts to relieve the symptoms of a movable kidney by an elastic belt, without simultaneously reconstructing the perineum, will hardly be satisfied with his results.

I stated at the beginning that the symptoms of sexual diseases and movable kidney which are similar or identical refer principally to the nervous system. There is even a similarity in the treatment. In neuroses, in epilepsy, for instance, movable kidneys have been extirpated. On the same principles displaced ovaries or diseased uterine appendages have been removed.

The propriety of this procedure has been the subject of repeated and lively discussions. The removal of a healthy movable kidney has been justly condemned, and that of the uterine appendages considerably restricted. If the salpingeo-ovaritis be purulent, then the removal of the diseased parts is fully justified. If it be of the so-called catarrhal variety, and the discomfort and recurring peritonitis greatly interfere with the patient's enjoyment of life or ability of earning a living, no plausible objection can be raised against the removal of the appendages. Those, however, who remove such uterine appendages under the supposition that the general nervous symptoms will disappear with the local inflammation, will meet with success and failure.

We have, up to the present time, no fixed rules upon which we can assure the patient in advance that the operation will relieve her of her nervous disorders. Those, however, who operate for this indication should not lose sight of the possible existence of a movable kidney or an insufficiency of the abdominal walls; and, above all, determine to what extent the symptoms will be favorably influenced by appropriate treatment. This must be directed not only to the movable kidney, but also to the general health and nervous system.

In the majority of cases, the symptoms of a movable kidney can be alleviated by a well-fitting elastic abdominal belt. The results are most favorable in those cases in which laxity of the abdominal walls exists. They are highly doubtful if the kidney be fixed in its abnormal position.

The favorable result of an elastic abdominal belt is, in all probability, chiefly due to the support given to the abdominal walls. A great variety of different and complicated belts have been constructed, with the idea of keeping the kidney replaced. But when we consider that direct pressure on the kidney is generally impossible, because the kidney lies behind the intestines, then the efficacy of belts with plates and springs is questionable. Heavy pressure is not well borne, and the kidney generally slips downward behind the belt. We must be satisfied, therefore, with the action of pressure, applied indirectly through the abdominal walls and intestines, to restrict the movements of the kidney. These requirements, as a rule, are fulfilled by an elastic abdominal belt, beneath which, corresponding to the position of the kidney, I place a cushion, or have it fastened to the belt. The elastic belt covers the entire anterior abdominal wall down to the symphysis and Poupart's ligament, and to prevent its slipping, is supplied with elastic bands passing between the thighs.

Exceptionally we meet women who are not benefited by an abdominal belt. Should treatment directed to the general health and nervous system also be of no avail, then nephrorrhaphy may be resorted to. We must be careful, however, that the real object of the operation—the fixation of the kidney—is properly carried out and a recurrence prevented. The capsule of the kidney must be incised, its edges and the kidney itself stitched to the deeper layers of the wound, in order to bring about an intimate union of the kidney with the posterior wall. After nephrorrhaphy the use of the elastic belt must be continued.

125 Second Avenue.

Perforation of the Intestine by a Spoon.—Dr. Libotsky reports the case of a woman in the eighth month of pregnancy who was suddenly seized with the symptoms of acute peritonitis. She died in a few hours, and at the autopsy it was found that the duodenum had been perforated by a silver teaspoon, and the spoon itself was found lying in the peritoneal cavity. It was ascertained, on inquiry, that the woman, while suffering from post-influenzal mania two years before, had swallowed the spoon with suicidal intent. She was taken at that time to Billroth, who examined her carefully but could find no hard body, and expressed a doubt as to the correctness of the report.—*Centralblatt für Gynäkologie*, November 26, 1892.

STRAY THOUGHTS ABOUT DYSPEPSIA.[1]

By A. A. YOUNG, M.D.,

NEWARK, N. Y.

"If it does no good it will do no harm," is an old saw, too often quoted and too often obeyed, in the practice of medicine. To follow such a doctrine is to reduce what should be the science of medicine to chaos, a condition from whence it sprung. Any substance taken into the stomach must be wholly inert; must be incapable of producing any irritation, either by its presence as a substance or by its solubility and absorption into the system, if it be perfectly harmless. There is no medium ground, for only a line exists between the normal stimulation produced by digestion, and the irritation produced by products of indigestion. We know, regardless of our acts, that there is a necessity for treating each patient individually, according to our best judgment, and not by a "set formula." The formula of a particular physician for his particular patient may do particular good, but for our patient under other conditions may be ruinous.

Indigestion means something more than mere inactivity of the digestive tract, something more than a loss of "tonicity" to the entire digestive system; the cause for such disturbance may, and often does, reside remote from the affected organ. To cure this disease, or rather to assist nature to eliminate it, the patient must be studied as well as the books, the cause must be known in each individual case, idiosyncrasies must be met, or the patient by the treatment may be hurried on to despondency, hurried on to a premature grave.

Most forcibly have these thoughts presented themselves while looking over the various formulæ for indigestion as given in our standard text-books, or perusing the various papers issued by the manufacturers of the so-called digestive ferments, the mode of manufacture or the formula of which is seldom, if ever, correctly revealed; but a description of the mode of administration is never abbreviated. The manufacturer apparently regards the physician as an automaton, an object to act only as he turns the crank, and we are prone to accept the condition, appear wise, and say to the world, "I use anything that effects a cure," an acknowledged "cut and dry" system, an insult to scientific inquiry.

Gastric juice taken by itself cannot perform its work fully and properly in stomach digestion; it must be aided by other fluids which are excreted during the process of mastication and deglutition; it must be aided by the purely mechanical action of the organ itself, and perhaps by other forces and fluids that we know not of.

As is well-known, gastric juice contains about nine hundred and ninety parts of water in one thousand, and the remaining portion is made up largely of albuminoid matter, known as pepsin, and a free uncombined acid with sodium chloride, and a few minor ingredients. It is a well-known fact that pepsin alone, without its auxiliaries, is almost worthless as a digestant. It is also well understood that when stomach digestion is completed this digestive ferment is absorbed into the system, to reappear again at its proper station, ready for new but similar work. This digestive ferment, if it be deficient in acid, is not improved, but made positively worse, by the addition of pepsin in any form or under any name; it is the acid that is demanded and should be administered; this is also true of every ingredient of gastric juice. This proposition may appear self evident, but it is often violated by the physician's acts Too often does he act upon this principle, the case in hand being "dyspepsia;" he looks wise and says: Dr. John Doe, my authority, says in "dyspepsia" give pepsin, and so it is done without a thoughtful why on our part, much to the damage of the prescriber's reputation; much to the damage of the patient's health. Give pepsin when the gastric juice is deficient in acid? No, but relatively decrease your pepsin and increase your acid. Give pepsin when the gastric juice is deficient in water? No, of course not, but relatively decrease the pepsin, acid, etc., and increase the water. This seems to be, and is, the only rational method of treatment. Give pepsin when the stomach is inactive, when the glands are partially atrophied, when there is a want of "tonicity" to the organ itself? No, for the stomach must perform its own duties, nothing can take its place. Nature hates a lazy member, and she will eliminate it by atrophy if there be nothing for it to do.

The digestive organs, it is true, must rest when tired, but the ingestion of food or pepsin gives no rest, both mean work when taken into the stomach; the latter, if it has nothing else to do, will digest, will devour the very organ that gave it birth; the former, if the digestive ferments or other vital forces are deficient, forms a rich soil for the development of sarcinæ, torulæ, and other products of fermentation. Even the process of fermentation may be retarded or suspended, and the process of decomposition substituted, producing thereby products that are absolutely poisonous either by direct contact or absorption.

It is not the intention to universally condemn the use of pepsin; far from it; it has its uses as well as its abuses. That it is a powerful digestant cannot be denied, but its peculiar property is not properly exerted, except it be aided by other agents and forces; without its auxiliaries it must be worthless at best. The process of digesting a hard-boiled egg in a test tube is a fine experiment to illustrate the digestive or solvent power of pepsin, but worthless as far as demonstrating its therapeutical uses and value. The test-tube is a far different thing from the stomach with all of its vital forces in action; the one represents inert matter incapable of giving impressions to, or receiving impressions from, the digestants which it contains; the other is an active, living membrane, endowed with a mysterious force, which life can only give to it, and of which the gastric juice may be impregnated.

Normal gastric juice contains well-marked germicidal properties, but in proportion as it varies from the normal, in the same proportion does it become a source through which infective diseases may be propagated by germ-development. The arrest of germ-development may, and I believe does, depend upon the free chlorides in the gastric juice; but the activity of the free chlorides may depend also upon the normal amount of the remaining constituents. Harmony here constitutes activity, healthy growth; the opposite constitutes disease, "dyspepsia," if you so choose to call it.

From what has been said, it is fair to infer that the peptones, in a majority of cases of dyspepsia, are worthless; more, they are absolutely harmful, for the activity of the stomach, as well as of the gastric juice, depends in a measure upon a limited or small amount of peptones; it is well known that when the food in the stomach is super-saturated with peptones, digestion is retarded until the latter are wholly or partially absorbed; hence, to lessen the necessity for work in the stomach, is to lessen its ability for labor. The constant use of predigested food must produce partial atrophy of both the muscular and glandular structures of the stomach. Predigested food may be theoretically good for the patient; he may be forced to take it against his will, but even then absorption and assimilation may be as impossible to accomplish, when nature says no, as to force a horse to drink against its will after being led to water. What good, then, comes from this pre-digested food, if it be not assimilated?

Milk alone given for nourishment, simple as it is, is harmful, though to it be added the lime-water, the pepsin, and the pancreatin, if the dyspeptic has a positive dislike for such food. The dislike for any particular kind of food is a warning of its positive harmfulness, and one, too, that cannot be overlooked with impunity. It reveals, in a certain degree, the inharmonious relation that exists between the so-called food, the digestive fluids, and those forces on which their activity, in a measure, depends.

[1] Read before the Central New York Medical Society, May 30, 1892, at Syracuse, N. Y.

Simple solution differs widely from normal digestion; the former is purely mechanical, while the latter is chemico-vital. It is in the latter process that pepsin plays an important part in stomach-digestion.

During this process it loses its vital force in the transformation of food, forming largely peptones, and when it has thus done its work, then, and not until then, it is prepared to pass the pyloric orifice and become reabsorbed, revitalized, and returned to the peptonic glands, from which it is again induced by the stimulating action of food. If gastric juice be deficient in any or all of its component parts, either quantitatively or qualitatively, if improper food be taken, or food taken at improper times, pathological conditions are at once induced which are expressed by that bewildering term dyspepsia, a term that represents little by being too general.

The treatment of this affection depends upon the proper differentiation of the conditions that produce it —conditions that are susceptible of classification, and without which it cannot approach even the dignity of a science, which is a classified knowledge. Isolated facts mean but little; comparative facts, though few in number, mean much. A classified knowledge points us to an intelligent, rational method of treatment with mathematical certainty; it says to us: "This is the way, walk ye in it."

TEACHING DEAF CHILDREN TO HEAR.

By LILLIE EGINTON WARREN,

NEW YORK.

THE education of the deaf-mute has opened a new field of late, and possibly my observations in a certain direction may be of some interest. Until a comparatively few years ago, deaf children were neglected, pushed aside, hidden from view; a humanitarian spirit lifted them out of the depths, and proved they were capable of some advancement; recently, however, scientific thought has been directed to their condition. Because a child did not respond when various sounds were made, he was pronounced wholly deaf, nothing could be done for him. Sufficient study was not given to his peculiarity, which might be called suppressed hearing. If he failed to recognize one sound, another was made before the first had reached his mind; in short, the length of time requisite to bring forth results when special pains have been taken, justifies the expression, slow hearing. These children hear slowly. This fact not having been realized, people jumped to the conclusion of total lack of hearing, and the deaf child has been given no opportunity to make the feeble efforts he might, if encouraged.

The work is extremely difficult. The pupil fails to appreciate what is being done, and has to be helped along contrary to his own wishes. He would much prefer to be let alone. Signs at first mean much more to him than articulation and speech-reading, but the latter is more attractive than the early attempts to listen. A small amount of hearing is of value in training the voice and opening the mind to an appreciation of words expressive of sound, even if instruction has to be given largely through the eye and the child forced to rely upon speech-reading. Of late, however, I have taught little children through the hearing alone, and am encouraged to persevere by the gratifying results. In instances where it was possible, co-operation at home by the parents, under my direction, has been helpful. Persistent efforts certainly have aroused these children's perception; there is reason to believe continued instruction will, in a measure, make up their loss, and with the development of mind, stronger power will be manifested.

Following are notes of some cases under instruction during the past year in my school for deaf children:

CASE I.—A boy who, at four years of age, after continued efforts to call his attention to sounds, began to notice the clapping of hands, whistling, and a trumpet. At the end of seven months' daily drill he hears a bell, the hand-organ, a canary's song, and the barking of a dog. He evinces much pleasure at singing when near, and turns quickly at the sound of a whistle in an adjoining room, behind closed doors. He can repeat readily a number of words when spoken near either ear, or at a distance of a few inches in loud or low voice. Some of the words have breath sounds, as papa, ship, whip, shoe, flower, and up.

CASE II.—A girl, ten years of age. She had no perception of sound until last December. At the end of five months she can hear and repeat a number of words; she can distinguish and give high and low notes very well. When standing outside of a room with doors closed, she can tell when the piano accompanies singing and when the instrument only is heard.

CASE III.—A girl, four years of age. Last October, when I saw her first, she noticed the ticking of a watch and heard the music-box and whistle. She made no attempt to repeat the sound of the voice, and could not locate noises. At the end of six months' instruction she can determine the source of sounds, and has learned people and objects have names. She can repeat readily and distinctly a number of words when spoken a short distance from her ears, as boy, sew, ball, bell, doll, and mouth. She has learned to repeat a little sentence, as "I see baby."

CASE IV.—A boy, ten years of age. When three years old, after continued practice, he could repeat a few words heard through a double speaking-tube. At five years he could distinguish about thirty words, if spoken slowly and very distinctly, but he became confused if two or more were repeated making a sentence. When nearly ten his hearing of speech had not improved to any extent, but he would turn quickly at the sound of whistles and bells. After the past seven months' careful work, he can recognize familiar words when spoken at a distance of six feet, and begins to notice what people say in the horse-car and other places. He understands and answers questions spoken some inches from his ear, and in his reading-lesson his pronunciation can be corrected through his hearing alone.

CASE V.—A girl, five years of age. When four she was considered wholly deaf. As her parents live a long distance from the city, her instruction has been carried on for a few months only at a time; enough has been gained, however, for home training to be possible. The child awoke gradually to an enjoyment of many sounds. Within fourteen months of her first lesson she has acquired quite a vocabulary, and has learned a number of sentences. She expresses herself by these words at all times, and uses the sentences properly. She has begun to answer questions, having at first merely repeated them.

It will be seen from the above that various noises are recognized and enjoyed before the human voice is noticed; the power to determine the source of these sounds grows by constant practice; words are heard for a while when spoken near the ear, their familiarity admitting of longer distance later; a memorizing of these words finally takes place; and even after they are first heard and repeated there is still a noticeable slowness, which is overcome gradually. How gradually can be appreciated by those only who have daily led the pupil step by step, against his will, through the early difficulties of learning to listen.

243 WEST TWENTY-FIRST STREET.

Badly Scared.—The Town Board of Franklin, Tenn., recently passed an ordinance forbidding the sale of watermelons in that place, and the local journal commends it for its wise precaution. It says, somewhat inconsequentially, that "the recent cholera epidemic in New York makes it incumbent on all cities and towns to exercise the utmost precautions to prevent the introduction of the germs into their borders." The town authorities had probably heard that the disease was spread through the water-supply, and they weren't going to take any risks.

COCAINISM.[1]

By J. B. MATTISON, M.D.,

MEDICAL DIRECTOR, BROOKLYN HOME FOR HABITUES.

Cocainism has been denied. Dr. William A. Hammond, speaking of cocaine before the New York Neurological Society, November 6, 1886, said "he did not believe any dose that could be taken was dangerous," and also asserted little power of that drug, except in cases of past or present addiction to alcohol or opium, to cause a "habit"—so called—a morbid condition not within the patient's power to control.

In a paper by the writer, read before the Medical Society of the County of Kings, Brooklyn, February 15, 1887, on "Cocaine Dosage and Cocaine Addiction,"[2] one case of cocainism, four deaths from single or repeated doses, and forty-six less toxic cases were cited; and, in a second paper, on "Cocaine Toxæmia," read before the American Association for the Cure of Inebriety, November 8, 1887,[3] three more lethal and seventy-three non-fatal cases were noted, more than one hundred and twenty five in all, making the most extensive *résumé* to that date presented, and impelling an editorial assertion from the *British Medical Journal*, that "if it were needful to produce more proof of the unsoundness of Dr. Hammond's statement, Dr. Mattison has effectually done this."

In a third paper, "Cocaine Poisoning," read before the New York Medico Legal Society, six more deaths and eighty more non-lethal cases were cited, making it needless to present added proof along the line of acute toxæmia from cocaine.

Regarding the other unfounded and unwarranted statement of Hammond as to the non-existence of cocainism, it has been well said that "one well attested case is worth a score of theories," and when the record of this paper is completed, detailing four cases of incipient, and thirteen cases of well-marked addiction to that drug—cocaine only, no past or present rum- or poppy-taking—leading to madness or death, it will, we think, establish a "returning board" behind which there is no going, and prove the perniciousness and danger of the opinion we have mentioned.

There is nothing on this topic in American medical literature except two excellent papers, by Morgan, of Indiana, and Zenner, of Ohio, each detailing a case. All other writers have referred to the effects of cocaine on those who were, or had been, alcohol- or opium-users. While cases of this mixed addiction have been frequent, now, happily, decreasing, those of cocaine only have been rare, and becoming more so; yet enough to show, beyond question, another danger from a drug that, along certain lines, stands peerless and alone.

Koller told the world what marvellous power cocaine has as a local anæsthetic—a blessing unique, and one worthy his lasting honor.

From beyond the sea came, too, a story of this drug which brought in its train degradation, despair, and death, for it was the ill-starred zeal of an Austrian enthusiast, Fleischiel, who, in his wild extravagance, declared that "with cocaine in the treatment of alcohol and opium addiction, inebriate asylums would be a thing of the past" a statement—not only untrue, but one which, going the rounds of the press at home and abroad, brought wreck and ruin to more than the world will ever know, and most of them, alas, members of our own guild.

And why? Because many an unfortunate who had gone down before the power of alcohol or opium built high hopes on this hapless assertion, and resorting to cocaine for relief, not only failed in that laudable endeavor, but added a new link to the chain of his addiction, compared with which the strength of the others was weak.

To best compass this subject let me offer you what clinical study has given us touching cocainism, its cause, consequence, and cure. Getting at once to the genesis of this disease, for such it is, we find that, like most cases of its less deadly congeners, opium and chloral, first given for relief of ill-health, body or mind, and persisted in, perhaps beyond legitimate need, it creates a demand for continued taking that will not be denied. Of the cases we shall offer, all began under conditions as cited; the only exception, if such it be, for it seems one form of mental ill-health, being that of the patient who used it to strengthen brain-power

While some cases, doubtless, though, perhaps, not so recorded, have had their rise in the morbid desire of erratic neurotics to test the effect of new drugs, coupled with the baneful outcome of mistaken teachings as to acute and chronic cocaine-taking, to which we have alluded, and, like the glamour of De Quincey's writings, which, beyond question, have lured men and women to destruction, that have doubtless impelled more than one, relying on these untrustworthy guides, to resort to its use.

The first recorded fatal case from acute cocaine-poisoning was largely due to the hapless surgeon's reliance on the asserted use by others of large doses without ill-effect. How many less lethal—may be—cases having a like origin? How many, all unrecorded, both acute and chronic, may be traced to the false teachings of Hammond and Bosworth, teachings so inimical to the welfare of person and public?

That is a query more easily asked than answered, but one which may well make us pause and ponder. Safe it is to say, in the light of past evidence and of present facts, it behooves every well-wisher of his kind to stamp out such dangerous doctrine with every clinical proof at command.

Shrady: "To some persons nothing is more fascinating than indulgence in cocaine. It relieves the sense of exhaustion, dispels mental depression, and produces a sense of exhilaration and well being. The after-effects are at first slight, almost imperceptible, but continual indulgence finally creates a craving which must be satisfied; the individual becomes nervous, tremulous, sleepless, without appetite, and is at last reduced to a condition of pitiable neurasthenia."

Shaw: "Once a man flies to cocaine for relief from 'cares that annoy,' he generally continues with such rapid strides toward such complete subjugation to its bewitching thraldom as but few will ever be rescued from by any power of will which they may be able to bring to their aid."

Everts: "It is a fascinating and dangerous intoxicant, the effects of which may be more difficult to counteract and renounce than are those of opium or its derivatives."

Hughes: "It is a remedy to be used with extreme caution and prudence internally, and the large doses reported as having been given are not ordinarily safe. It will bear watching. It crazes and kills quicker than opium. The possibilities for immediate harm are not only great, but the likelihood of remote damage when tolerance is established is not small. The cocaine disease, more pernicious than the morphine neurosis, is the certain entailment of its frequent administration, and its thraldom is far more tyrannical than the slavery of opium."

Clark: "This case," cited later, "has furnished me such positive proof of a lurking danger in the use of cocaine that all the negative evidence or hypothetical assumptions published or adduced cannot have the least impression in causing me to relax for an instant the most rigid supervision of every patient to whom I in any manner administer or apply the drug."

Zenner: "Cocaine, even to a greater degree than alcohol or morphine, weakens the will and produces character degeneration."

Ring: "I would not be willing to take the responsibility of a like continuance"—case noted—"with any patient; neither would I put it in the hands of one to be

[1] Read before the District of Columbia Medical Society, Washington, December 24, 1890.

[3] La Tribune Medicale, Paris, January 1, 1888.

used at his discretion. Take a man who is ill, downhearted, unable to work, and subject him to my experience, and what would become of him? Would he not be in imminent danger of becoming a cocaine *habitué*?"

Clouston: "In cocainism the craving is, perhaps, greater than for any other stimulant or narcotic whatever, and it is the most absolute destroyer of inhibition and the moral sense that we yet know."

Morgan: "Cocainism is the worst of all known drug diseases, and the most rapid in its action."

Mattison: "I think it, for many, the most fascinating and seductive, dangerous and destructive, drug extant. It may be toxic, sometimes deadly. It may produce a diseased condition—in which the will is prostrate and the patient powerless—a true toxic neurosis, more marked and less hopeful than that from alcohol or opium."

The most ensnaring way of taking cocaine—or any narcotic—is subcutaneously, and this is the usual form of chronic using. We have, however, the record of cases where its inception was by mouth, as a stimulant, as an external application to subdue the pain caused by eruptions, as a local anæsthetic, or as a nasal spray. This phase of the subject is soon disposed of; most cases have had their origin in a legitimate use of the drug, thus proving, with fullest force, the paramount importance of personal professional care to insure complete quitting when the proper need is ended.

We now enter upon another phase that is appalling, for of all drug-wreckers of mind and body cocaine leads the list. Taken hypodermically its effects are transient, and coupled with a fascination peculiar to itself; some *habitués* get to taking it very often—repeating the dose every fifteen or twenty minutes, for hours. This rapidly reaches a large aggregate—sometimes sixty grains a day—and easily explains the havoc that soon ensues. Its destructive energy is unique. For swiftly pernicious, profoundly perturbing effect on functional well-being, it has no equal, and as an acute killer of moral sense it stands alone. Well has it been styled "the devil's own drug;" well has it been said, "he must gloat with special delight to see a poor wretch tampering with cocaine;" and truly has Erlenmeyer, Germany's highest authority along this line, written: "He who has seen the sudden, lightning-like, mental, moral, and physical destruction of one who has given himself up to cocaine, will let every optimism array itself against it."

The diagnosis in well marked cases is not difficult. In some the cause is patent; in others, especially morphia cocainists, if concealed, a consensus of peculiar psychical and physical symptoms, confirmed by a few hours' vigil, and made complete by finding cocaine in the urine, prove the disease beyond dispute.

To tell, most tersely, the sequences of chronic cocaine-taking, we shall note its effects in detail.

Digestion.—In the larger number of cases the earliest ill results refer to this function. Of all drug destructives cocaine is the most absolute anorexic known. Fully under its influence all desire for food is lost—patients going for days without a morsel. As might be expected, this failure in supply does damage along nutrient lines, and coupled with its direct pernicious effect on glandular activity brings about emaciation more quickly and in larger degree than any other known drug. Thirst, too, is in abeyance, but both may return when the toxic effect is lessened or suspended.

The buccal cavity, in some, becomes dry and tender, the pharyngeal muscles painful, deglutition difficult, and the gums, tongue, and throat take on a peculiar reddish hue. Other signs of gastric disorder may present—odorous breath, coated tongue, eructations, and painful digestion. In the bowel it induces torpor—no action for days, and then only by superactive purgation—or forceful, spasmodic action, with fæces hard and dry.

Respiration.—Vaso-motor defects in the system are hurried, depressed breathing, and dyspnœa—especially on effort—due, in part, to direct effect and partly to impaired general tone.

Circulation.—Much more marked is the toxic action on the heart, and it is always the first effect of a full injection. The pulse quickly rises to 100, 120, or even 130, remaining so a half hour or more, and then, through one or two hours, gradually reaching normal, unless requickened by a new supply. It has been known to remain 100 to 120 for months together. It may continue regular, but becomes fuller and rapidly quickened by effort. All this from vaso-motor paralysis, and this circulating condition is a source of constant danger, for an overdose may speedily prove fatal from heart palsy; and another point worth knowing, as Erlenmeyer has stated, this continued vascular relaxation makes extra-hazardous chloroform anæsthesia in cocaine *habitués*.

Liver.—Fully jaundiced, or a pasty or yellowish-white color evidences the hepatic derangement; sometimes bronzed—Addison's disease like. A peculiar cadaveric complexion, better appreciated when seen than from any description, sometimes presents.

Kidneys.—Increased action at first; later largely diminished. Sugar and albumin may be present; oxaluria; specific gravity high. On the bladder a semi-paralysis of the muscular coat, as in morphinism.

Skin.—Irritation or inflammation from the hypodermic-taking is rare. The immediate circle of the injected part is partially anæsthetized, and this may be, in part, protective against a common sequel of morphia-injecting. Later, boils, due to the general dyscrasia, may appear. The vaso-motor relaxation before noted obtains here, and sweating, profuse and prolonged, especially on exertion or excitement, is noted. Cold, clammy, limb perspiration, with body burning, or skin dry, cracked, and pallid, may ensue, and temperature may be depressed.

Sexual.—Cocaine, like opium, may first stimulate this function, but excess soon brings the effect of over-goading, and, sooner than with the poppy salt, comes loss of desire and power, and impotence complete. This, purely functional, is quickly and fully recovered from on quitting the cause.

Nutrition.—Next to the nervous system and brain, this is the field in which cocaine does its wickedest work. No other drug equals its tissue-wrecking power, emaciation from continuous use being constant and decided, sometimes extreme. Two factors do this. First, the effect of the drug in abolishing all food desire cuts off the needed nutrient supply. Added to this is its pernicious result on glandular action, which, enormously increased by its stimulating effect, not only disposes of all nutrient material ingested, but as that—being so far below normal, as has been noted—is insufficient, the body tissues are levied on to correct the accelerated metabolism and consequent defect. To a minor extent this defect is observed from single or limited doses, for they will cause salivation, lymphatic swellings, and even swelling and hardening of the mammary gland; but, largely and steadily taken, this ill result is greatly intensified, and makes one of the most marked and disastrous sequelæ of excess. According to Maerkel, on this vastly increased cell-action depends the stimulant effect; "but exactly in this accelerated metabolism lies concealed the same danger, perhaps even a greater, as in every other extravagance in the organism, constructed and operated on principles of the greatest economy. From temporary use of the drug injurious effects on the organism are little to be feared, because the waste of nutrient material can, in great measure, be replaced; but when the drug is habitually used, it is very improbable that the supply of nutrient material carried to the glands is sufficient to correct the defect caused by their increased action. To confirm this view we have the fact that, in South America, persons who use coca die mostly of phthisis, which is brought on partly by lymph stream disorder and metabolism, and in part by premature wearing out and consumption of parenchymatous cells of the lymph-making tissues."

Nervous System.—As might well be expected, here is the second largest field for destructive work of this drug. This, like its action on nutrition and the brain, is largely due to its peculiarly fleeting effect, and which compels such frequent—more largely than any other narcotic growing by what it feeds on—increased taking. Many opium *habitués* maintain a fair avoirdupois and nerve status for quite a time. So may chloral-takers, but not so with cocaine. It ravages along all nervous lines, and so, leading up to the higher brain centres, stamps its ruinous power unique. At first merely over-activity; then the reaction and wreck sequelling hyperstimulation; soon comes the signs, known in part to you all, of typical wretched neurasthenia, all the more wretched by the consciousness of the miserable victim that he is daily adding to his anguish by the pressure of a power he is helpless to resist. Among these symptoms, with some, is a peculiar unrest—almost constant movement—which becomes in marked cases such as we have never noted in poppy or chloral *habitués*. Soon insomnia, absolute and intense, ensues. Nights and days together patients go without sleep, and when it does come, it is often robbed of its restfulness by horrid dreams.

Fugitive pains—sometimes shock like in the limbs—not so distinct, decided, and localized as in chloralism, occur. All the special senses become affected. Sight: Brilliant eyeballs, dilated pupils, light intolerance, object distortion, and hallucinations. One patient now under treatment had not been in her room a day before she had rearranged the furniture to keep out a new-found "Peeping Tom." Touch: Over-sensitive; hot and cold chasing; air-draughts, like a storm-blow; bugs and reptiles race each other; and there "the touch of a vanished hand." Hearing: Over-acute and hallucinatory—"the sound of a voice that is still." Taste and smell are impaired, blunted, distorted, hallucinated.

In this connection may be mentioned one symptom which we have never noted in any drug *habituê* other than cocaine, and which Heinemann thinks due to the action of that drug on the skin, though we regard it from morbid brain action. It is the patient's idea of some substance—worm, or glass, or splinter, or drug—under the skin; notably the finger-tips, for which they'll dig with knife or needle till the parts are raw. Magnan cites such cases. One always scraping his tongue and thought he was extracting little black worms. Another made his skin raw trying to extract cholera microbes, while another was constantly looking for cocaine crystals under his cuticle. One patient, a physician, now under my care, declared his microscope disclosed a parasite; and his wife had in lesser degree the same delusion. This symptom seems *sui generis*, and presenting so often affords added proof in suspected cocaine-taking, and illusions and hallucinations run riot, and, added to varied varying delusions, soon make the cocainist a fit subject for a mad-house.

While the ravages of cocaine along somatic lines excite surprise and alarm, one stands still more appalled at its ruinous "lightning-like" effect on the higher brain-centres—ideation, intellection, and the moral. Here it has no peer. Here it proves itself "the most powerful and devilish drug which it has been the misfortune of man to abuse." Here it shows itself unique for "debasing enslavement" of volition, and for "diabolical and indescribable general demoralization." Toxic brain effects appear soon in some cases; as a rule, not till the doses are large, or the taking excessive. Among the earliest are hallucinations of most, or all, the senses to which we have alluded. These illusions and delusions, sometimes illusions first are added to and intensified by the others. Take this triple deliriant factor, and little wonder the cocaine lunatic finds himself compassed by a legion of horrors that drive him to distraction. These are realized ofttimes by the patient as being mythical and absurd, yet he is hopeless to control them. He may discuss things intelligently, yet cannot be convinced of his vagaries.

The most prominent hallucinations relate to hearing; the most important—regarding diagnosis—to touch. All—illusions, delusions, and hallucinations—in marked cases are mainly of persecution. Here, again, is a point of diagnostic import. In other drug manias—morphia and chloral—impulses to kill are largely suicidal. Not so cocaine, but homicidal, distinctly, and almost without exception. These rise from two causes—one fear, horrible, ever-present fear, either of an avenging pursuer, the outcome of a previous delusion as to some criminal act, or to escape persecution; to resent proposed restraint, or revenge some fancied grievance. This impulse to kill seldom leads to assault unarmed; but making himself a sort of walking arsenal the frenzied cocainist, without purpose to harm any special person, may rush through house or street, firing, regardless of result. Of course this delusion will likely be more special and deadly in one of normal revengeful spirit.

The aural hallucinations cause more unrest and distress than the visual, and the unseen enemies or burglars may lead to reckless shooting. A case of that kind is now under my care. No ill-will; no sense of persecution; no avenging desire, but a fancied burglar—an active fusilade and badly damaged surroundings. Saury is right in speaking of a special delirium—essentially hallucinatory—due to cocaine. Disturbance of ideas is not primary; it confines itself constantly to sensorial troubles. All the senses may be affected, but in unequal degree. Disorders of general sensibility are markedly prominent; then come hallucinations of sight, then hearing, smell, and taste, all of which may be varied and painful.

Ideation and intellection become weak and distorted. Visionary schemes, absurd business ventures, and wasteful extravagances may obtain. Another special feature—especially in physicians—is sometimes marked even in incipient cases, as will be noted later: a peculiar mania as to the panaceal powers of cocaine—a universal balm, lauded loudly for the most varied diseases. So striking is this in some cases that it may sway the diagnostic balance in suspected cocaine-taking.

Under the lashing effect of this drug ideas are evolved rapidly, and find expression in surprising volubility. The loquacity is sometimes extreme, and if noted after a supposed cocaine-quitting may well excite distrust. Especially common, too, as Erlenmeyer has said, is a certain prolixity in conversation and correspondence, which, when united with a weakened memory, may lead to the greatest embarrassment and confusion. General listlessness and inaptitude for brain-work are notable. The brain spur soon expends itself on doggerel verse or trashy prose.

On the *morale* the results are deplorable. The *personale* of some cocainists is greatly changed. One cleanly, tidy, almost Brummell like, becomes dirty, careless, unkempt to a degree. The nastiest patient under my care was a cocaine *habituê*.

Of more import is the change in higher attributes. Lying—more than with opium—selfishness, and malicious intent, if the drug be debarred. The claims of friendship and affection are disregarded; family ties, the care of children, social and domestic duties, are neglected, while religious duty and the authority of ritual superiors are ignored and denied.

After this recital, gentlemen, you may think me an alarmist, a pessimist. Yes, truly so, everlastingly so as regards cocainism, speaking whereof I know, and quite agreeing with Erlenmeyer, who wrote of it: "It is a sorrowful picture I have drawn, but I fear that I have not selected colors dark enough." The prognosis of cocainism is bad. The prospect of lasting cure, except under prolonged treatment, is not good. Acute recovery can usually be assured and secured; but the risk of recurrence is large—more so than any other toxic neurosis, save, perhaps, morphine-cocaine addiction.

Treatment.—In recent cases the drug can be quit at

once, and the resultant reflex irritation met with phenacetine, ten to twenty-grain doses, to control pain and unrest, and chloralamid, thirty to sixty grains, to secure sleep. Should more potent remedies be needed, one to two-grain doses of codein subcutaneously. As an anodyne, paraldehyde, thirty to one hundred and twenty minims, in capsule or elixir, or sulphonal, twenty to forty grains, with or without hydrobromate of hyoscin, one one-hundredth to one-twentieth grain as a soporific. Later, galvanic and faradic *séances*, with internal tonics and favoring conditions for several months are required.

In marked cases more robust measures are essential. If the body well-being be not greatly impaired—otherwise a tonic course should precede rapid reduction—six to ten days, coupled with a minor degree of preliminary sedation after the writer's method, "The Treatment of the Morphine Disease," can be used. As a partial substitute for the cocaine, caffein-sodii benzoas, one to five grains hypodermically, will be found of value, and for the pain and unrest, as well as insomnia, phosphate of codein in full doses, two to three grains subcutaneously, or double by mouth, will prove effective. If needed, narcein will add to the codeine effect. Morphine should not be used. Alcohol should be withheld unless imperative. If so, it may be given as alcohol—not brandy or whiskey—and always with milk or other food, or hypodermically. The risk, in treating these cases, of causing a new form of drug addiction should never be forgotten.

After the acute effects of quitting have subsided, the same indications for treatment will present as after morphine-ending, to be filled along like lines in the same way as detailed in the writer's paper before mentioned.

In some cases, more so than in the morphine disease, restraint will be needed. For reasons stated this should be as mild and brief as is consistent with the welfare of the patient, the object being to re-educate and restore the depressed will-power, and this can be done in some cases by mildly coercive measures rather than the reverse. With others, however, absolute and prolonged restraint is imperative. The importance of a protracted roborant *régime*, varied and constant, with freedom from work and worry, obtains more largely in this and morphine cocainism, than any other drug disease. The peculiar, overmastering fascination of cocaine, its strong, almost resistless, tendency to retaking in the early weeks or months of abstinence make this essential. In marked cases six to twelve months, or even longer, must be taken in which, if at all, to get thoroughly well. The importance of prolonged hygienic care and favorable surroundings, after active medical treatment is ended, in these cases, cannot be overestimated, and *they are absolutely essential* to effect a lasting cure.

THE CHINESE AND THEIR PECULIAR MEDICAL IDEAS.

By I. E. COHN, M.D.,

PORTLAND, ORE.

LATE SUPERINTENDING SURGEON NORTHERN PACIFIC RAILROAD.

My former position as chief surgeon of various railroad companies on this coast has thrown me in contact with a people rarely met with by the general practitioner, namely, the Chinese. It is very rare that they employ other than their own people to administer to their wants. During the construction of the Northern Pacific Railroad and the Oregon Railway and Navigation Company so many accidents and diseases broke out in their camps that they had to rely on the services of the companies' medical staff, and by degrees we got an insight into their medical customs, for surely it cannot be called a "science." That they have their own medical schools and a rigid method of examination and studies is told us by the best authorities who have travelled in that still, to us, unknown and uncomprehended land. There may be some men educated in medicine, according to their ideas of education, but they are rare in this country. A well-versed Chinaman told me that the "Chinese doctors" of this country are what we term "quacks," and knew nothing, and not one of them had ever passed an examination in their own country. Having therefore their own physicians they consequently maintain their own drug stores and Materia Medica. Some of these "Chinese doctors" advertise quite extensively in our daily papers to cure all diseases human flesh is heir to, and to the shame of our own people, be it said, they will consult and conscientiously take treatment at the hands of these "necromancers." These men have absolutely no anatomical knowledge, and therefore as a necessary consequence know nothing of pathology. They claim the body has two separate and distinct hearts, five livers distributed throughout the various parts of the abdomen; that there are five sets of intestines, and that all is presided over or regulated by seven emotions.

Their Materia Medica is composed wholly of vegetable and animal matter; the most of it imported into this country coming in roots, or if prepared in China, in wax-balls. The vegetable kingdom contributes most freely, and makes up the greater bulk of their drugs. As examples of the curative agents taken from the animal kingdom I will only mention a few, such as dried powdered hides of rattlesnakes, ox and dog gall, dried shrimps, scales of certain fishes, and dried blood of various animals, among them the rat. This is a positive assertion, and should not be taken *cum grano salis*. Their mode of administering medicines is either in a tea, a plaster, or, in case these wax-covered boluses are prescribed, the cover is broken and the contents swallowed. In examining their patients they always examine the radials of both arms. They claim, as stated, that there are two hearts, separate and distinct from each other, in the body, so take the beat of each; but this is more probably an archæological procedure based upon the old doctrine of "digitus cordis" and "digitus medicus," which might very easily have been brought to China from the Alexandrian school

They ask for no symptoms, not even a question regarding your pains or aches, and surround themselves with mysticisms of all kinds. Their conclusions are always the same: "Take my tea and you get well." An ill-smelling package of finely chopped up stuff is handed you to brew into a tea. One of the oiliest impostors of this class was the late Dr. Lai Po Tai, of San Francisco, who died a millionaire, his fortune having been made by working on the credulity of the California public. Nor was this patronage confined to the ignorant, for his carriage could be seen daily in front of the mansions of the rich, on "Nob Hill."

The knowledge of surgery of these men is, to say the least, crude. No matter what the ailment or condition, a plaster of some kind is put on. I have never known of an instance of their using the knife. It was my good fortune once to be present at the dressing of a fractured leg. They placed a peculiar kind of clay into a wooden bowl, brought in a lot of chickens, and, with incantations, severed their heads and allowed the blood to flow on the clay, which was mixed therewith. This was applied direct to the fractured limb without any attempt at reduction. Bandages were then applied, and finally small bamboo strips entwined in the bandage, enveloping the whole as if in a wicker basket. Another chicken was confined under the last turn of the bandage, and the head severed and the blood allowed to soak through the bandages. After this the bird was removed and the leg dressed in the most approved Chinese fashion.

As a stoical race they beat the Indian. You can cut them all to pieces, and they will lie perfectly still and not a groan will escape them. I have repeatedly operated on them without the use of an anæsthetic, having had the administration refused. I remember a case in particular where I deeply invaded and laid open the cervical region to remove a large tumor. In an accident on the Northern Pacific Railroad, where quite a large number

of limbs had to be amputated, we had quite a struggle to administer chloroform, and some had limbs amputated without it on account of their stubborn refusal, but in never an instance was an outcry made. It actually seemed superhuman.

They have a "god" for every emergency, and only value life on the basis of what there is in it, and are fearless of death, which has for them no terrors. This explains the fact that people living among them rarely, if ever, see a maimed or crippled Chinaman. In the railroad accident before referred to the number who had to submit to amputation of limbs was seventeen, and not one of them survived. They commenced to die at a period of convalescence when about to be discharged from the hospital. In the case of the first death no notice was taken of it, and no suspicions aroused. The next morning more followed in the same mysterious manner, and I concluded to solve the matter. With Drs. Davie and McMahon I made post-mortem examinations and found invariably evidences of opium-poisoning. I ordered the wards searched high and low, and placed guards over them, but all to no purpose, every one of them died in the same manner. Opium was smuggled in to them in spite of the closest watch. Some time thereafter, in conversation with a leading Chinese contractor, I expressed my indignation, but was coldly informed that they were better off dead than alive; that they were no longer able to work and care for themselves, but would become a burden to themselves and friends; that death was far preferable, and that they had demanded the drug to put an end to the miserable existence which stared them in the face on leaving the hospital. I have since had similar pleasant experiences with them.

In this connection I wish to say a few words on the speedy healing of wounds on these people, and which must be due to their diet and habits of bodily cleanliness. From early youth they are constantly in the water, and you find the lowliest washing their bodies twice a day. Their diet is mostly vegetable, in which rice and tea form the foundation, to which are added green vegetables, as young turnip-tops, spinach, kale, or similar garden truck. Very occasionally they add to this oysters, fish, pork, and fowl, principally chickens or ducks. Beef, mutton, and veal they use in no way. Possibly this may explain the quick healing power, which is marvellous. The tissues of their bodies cut differently, that is, they feel differently under the knife, than in the Caucasian subject. They are more dense and elastic, and not so flabby.

The peculiarities of this race extend to the lying-in-room. The patient will not allow herself to be placed in a recumbent position during labor, but insists upon sitting on the edge of a chair, or between two chairs, and maintains that position until labor is complete. The cord must be cut with a piece of glass or broken china, a new cup being generally sacrificed for this purpose. The tying of the cord is also peculiar. You will be allowed to tie it as close to the body as you may desire, but you must leave at least three inches beyond the ligature. The after-birth is invariably burned, and the patient is placed in bed a few hours, her buttocks resting in a plate or pan filled with ashes, so that every discharge may run into and mingle with the ashes. This is also thrown into the fire. They resist vaginal douches or any interference, and it is a hard matter to get consent to make an examination.

They believe they can diagnose the stage or progress of labor by the condition of the pulsation of the middle finger of the right hand. As labor progresses they hold the pulsation increases, and just before the delivery of the head it is felt tumultuously in the ball of the finger, but ceases with delivery. They use no bandage, and if you call the next day you will find your patient (belonging to the better class) up, dressed, and entertaining her friends, just as if nothing strange or out of the usual course had happened. I have never known or heard of any serious complications in Chinese lying-in chambers. The child is invariably nursed by the mother, who always has a sufficiency of nourishment for it. If in case of a female infant you should call and find it had mysteriously disappeared, as often happens, especially when the family is large, you can form your own conclusions. That female babies are got away with in China among Coolies is well known, and this practice has also been imported to this country. Under the present restriction laws regarding Chinese immigration these female babies will hereafter most likely be considered the most desirable property, and whereas until now they were considered a drug on the market, they may become, in America at least, a source of anxious solicitude and desire, since the possession of one of them will enrich the family.

In conclusion, I would say a few words regarding the Chinese Materia Medica. I do not wish to be understood as denying the possibility of their possessing many remedial agents that may be of value, in fact we know better. We have gathered from all nations more or less, and it is not improbable that we could derive from them some very important knowledge and valuable remedies, which to us are totally unknown. A strict investigation into the physiological and therapeutical action of some of their remedies might be of great value, and would surely be of much interest to the civilized world.

Progress of Medical Science.

Vaccination for Hog-Cholera. — Dr. Metchnikoff draws the following conclusions from his investigation into the immunity of rabbits vaccinated against the microbe of hog-cholera: 1. The serum of rabbits vaccinated against hog-cholera does not show any bactericide or antitoxic properties. 2. This same serum does not possess the power of attenuating the virulence of the microbe of hog-cholera. 3. In spite of the absence of these three properties, the serum of vaccinated rabbits protects other rabbits from fatal infection with the bacteria of hog-cholera. 4. This preventive property is not found in the fluid obtained from œdema caused by arrest of circulation. 5. The bactericidal properties in vaccinated rabbits reside in the phagocytes. 6. The pus of vaccinated rabbits retains virulent microbes for a long period. 7. The organism of vaccinated rabbits is very sensitive to the toxines of hog-cholera and presents no antitoxic properties. 8. The phagocytes play a very important rôle in the resistance of vaccinated rabbits. 9. They play an equally important rôle in the resistance of non-vaccinated rabbits which have been treated with the preventive serum. It is probable that this liquid exercises, under these conditions, a stimulating effect upon the phagocytes.— *Annales de l'Institut Pasteur*, May 25, 1892.

Antimony in Skin Diseases.—Drs. Jamieson and Douglas (*Edinburgh Medical Journal*, June, 1892), after some investigations and the cure of a case of psoriasis inveterata and one of dermatitis exfoliativa, arrive at the following conclusions: 1. Antimony lowers temperature in some conditions of the skin associated with hyperæmia and dryness of the surface. 2. Its influence on tissue waste, as estimated by urea and urine excreted, is not, under the circumstances detailed, a noticeable one. 3. It softens the skin, augments insensible perspiration, improves the nutrition of the integuments, diminishes hyperæmia, and lessens the tendency to premature and excessive epidermic exfoliation. 4. While advantageous in the congestive stage of acute eczema, it is contra-indicated in Brocq's second stage; it may again prove serviceable in the stage of successive desquamations. 5. It is likely to be of use in cases where there is a functional nervous cause; it may prove of value in diffuse scleroderma, and possibly in myxœdema. 6. As compared with arsenic, authors are pretty generally agreed that the latter is valueless in conditions of the pityriasis rubra type. 7. Arsenic restrains

the tendency to form bullæ in dermatitis herpetiformis and pemphigus, and sometimes cures psoriasis, but may apparently convert a psoriasis into a pityriasis rubra. 8. Arsenic in some cases renders the skin muddy, dull, and earthy, and it may give rise to keratosis, which again may pass on to epithelioma. Such results have not so far followed the administration of antimony. 9. The action of antimony may be contrasted with that of pilocarpine. Pilocarpine produces a copious perspiration for a brief period, while antimony bathes the epidermic cells continuously in a gentle moisture.

Variola, Varioloid, and Varicella.—In the *Jahrbuch fur Kinderheilkunde*, 1892, page 427, there is a survey of these three conditions. Biedert finds that there is one form of varicella in which marked constitutional disturbances exist, not only in little children, but in those approaching adolescence. Sometimes it occurs in adult life. This severe varicella is with difficulty distinguished from varioloid, especially varioloid that has been mitigated by previous vaccination. In variola the period of contagion begins after the period of eruption. Immunity conferred by vaccination has a variable duration, sometimes seven years, sometimes longer. It may cease in one or two years. Immunity begins a week after vaccination.

Physiological Action of Massage upon Human Muscle.—In the *Archives italiennes de Biologie*, 1891–92, page 225, Maggiore's experiments with Mosso's ergograph lead him to the following conclusions: 1. Massage applied to a muscle at rest increases its resistance to fatigue, and modifies and delays fatigue proper. 2. In certain cases the good effects of massage are in proportion to the length of time that it is given. 3. Massage prevents in muscles the accumulation of fatigue-products due to work that is too closely consecutive. 4. Percussion and rubbing are inferior to kneading and to mixed massage; that is, to the alternate application of these three methods. 5. In muscles weakened by fasting, massage increases resistance to the effects of work. 6. Upon muscles fatigued or weakened by general causes, as forced marching, watching, brain-work, massage exercises a restorative action. 7. Massage has no good effect whatever upon muscles in which the circulation of the blood is suppressed.

Rachitis.—One of the books of this year is Comby's study of rachitis, a disease that has not been revolutionized by the microbian doctrine, that is to-day the same entity as it was yesterday, and will, in all probability, remain the same forever. In the author's opinion all cases of genu valgum, unilateral or bilateral, are due to rachitis. Hereditary syphilis as a cause of rachitis Comby rejects utterly, believing only that it may influence digestion unfavorably. The chief factor in the production of rachitis is improper food. This results in dyspepsia and dilatation of the stomach. Even when the constitutional trouble is cured, this dyspepsia often remains. All rachitics in adult life are dyspeptics. Treatment consists of plain or phosphated cod-liver oil, preparations of phosphorus, sea-baths or salt-baths, and strict hygiene. Most cases recover.

Troubles of Salivary Secretion in Mumps.—Simon, in the *Revue générale de Clinique et de Thérapeutique*, 1892, No. 15, calls attention to the fact that during recovery from mumps there is frequently profuse salivation, sometimes so exaggerated as to constitute a true complication that may last several months. The saliva secreted is thicker than normal. Neuter sulphate of atropine is the drug best adapted to relieve this condition.

Neoplasms of the Vagina.—In the *Centr. f. Gyn.*, 1891, No. 41, Strassmann reports two cases of tumor of the vagina, a condition comparatively rare. Neugebauer has collected thirty-five cases; Kleinwächter, fifty-three; and Breisky, in 1886, five more. Strassmann's first case occurred in a woman, forty-one years old, married, sterile, and suffering great pain due to small tumors the size of a bean in the recto-vaginal cul-de-sac. Removal and microscopic examination of these small tumors showed them to be calcified fibromata. In the second patient, a woman, thirty-four years old, a tumor as large as a hen's egg was found in the anterior portion of the vagina, implanted upon an extensive base. This proved to be a soft fibroma, rich in blood-vessels and lymphatics.

Objective Signs of Neurasthenia.—In the *Munch. med. Woch.*, 1891, Nos. 50, 51, 52, Loewenfeld advises that all cases of neurasthenia be examined for the following signs: General nutrition remains unimpaired unless there is dyspepsia. The skin of the face and chest reddens at the least emotion, the ear and cheek sometimes being deeply injected. Narrowing of the visual field is exceptional. There is excessive mobility of the pupils, that grow smaller and larger not only on account of ordinary physiological excitation, but from psychic impressions as well. Inequality of the pupils, occasionally present, is transitory. Muscular phenomena are complex. There is inability to close the lids completely, weakness of movement in convergence, motor insufficiency in hands and arms, and fibrillary twitchings. Reflexes are often exaggerated. Loss of knee-jerk is not a symptom of pure neurasthenia. Nervous excitability is exaggerated, especially that of the optic nerve. Troubles with the voice, speech, and writing, are due to lessened resistance of the muscles to fatigue. The heart-beats are either increased or diminished. Vascular tone is lessened, and the arteries are lengthened in serpentine form. The motor force of the stomach is diminished, and there is more or less hyperacidity. Eructations, constipation, and nervous diarrhœa complete the dyspeptic symptoms. General hyperidrosis is common, though sweating may be confined to the hands and feet, or to the head during sleep. The urine nearly always undergoes some change. There may be mucus in it; polyuria, phosphaturia, or oxaluria may exist.

Primitive Splenomegaly.—According to Bruhl, in the *Archives Générales de Médecine*, June, 1892, primitive enlargement of the spleen is a variety of pseudo-leucæmia. It is characterized by this special enlargement, by diminution of the red blood-corpuscles without increase of leucocytes, and absence of glandular swellings. There is nearly always some enlargement of the liver. Anatomically, the essential lesion is splenomegaly. Histologically, the glomeruli Malpighii show marked alteration, being scarcely recognizable.

Troubles of Dentition.—In the *France Médicale*, August 19, 1892, there is reference to Gibert's recent paper upon the foregoing subject, which embraces an analysis of observations made upon one thousand children artificially fed, and upon five hundred infants naturally nourished. The author concludes that children brought up on the breast are almost entirely free from diseases attributed to dentition, only two of the five hundred showing any such abnormity. But among the other one thousand there were 58 cases of simple stomatitis, 113 of ulcero-membranous stomatitis, and 28 cases of convulsions. Dentition is never perfectly accomplished without the act of sucking the maternal nipple, which favors the physiological waste of the gums. There is no such thing as diarrhœa due to dentition.

Cocaine in Tinnitus Aurium Due to Middle-ear Disease.—In *Siglo medico y Rev. laryngol.*, 1892, No. 14, Carralero advocates injections of a four per cent. solution of cocaine into the Eustachian tube. This brings about excellent results, especially when hyperæmia and catarrh of the tympanum are present, together with congestion of the labyrinth, hyperæsthesia of the middle and external ear, or proliferous inflammation. These injections are used every day at first, then every two or three days, by means of Itard's sound.

Infectious Erythema in Diphtheria.—Mussey's *These de Paris*, 1892, treats of this subject. There are several kinds of erythema more or less constantly present in diphtheria—the polymorphous, the rubeolic, the scarlatinoid, and the desquamative scarlatiniform. Often these are transitory. Some are difficult to recognize, as purpuric erythema. Such eruptions are of graver import in regard to prognosis when occurring late in the disease.

Respiratory Prodromata of Typhoid Fever.—In the *Révue laryngol.*, 1892, No. 14, Boyer states that sometimes the earliest manifestations of typhoid fever are in the respiratory tract toward the end of the first week, consisting in catarrhal inflammation of the throat and nose that may also implicate the Eustachian tube and the middle ear. Oval or circular ulcers, superficial and without exudate, are found in the respiratory passages. They are similar to the intestinal lesions, and contain Erberth's bacillus. Not of much importance in themselves, these ulcers are of moment in differential diagnosis and prognosis. According to Miller, they indicate grave conditions. A case is cited in which acute laryngo-pharyngitis appeared simultaneously with the intestinal lesions of typhoid, resulting in death in forty-four days.

Results of Gonorrhœal Infection in Women.—Von Rosthorn, in the *Präger Medicin. Wochenschrift*, 1892, states that the prognosis of gonorrhœal infection is favorable as long as the poisonous process does not invade the cervix. When this happens, rapid extension of the inflammation results, an "ascending gonorrhœa" causing marked changes in the genital tract and surrounding tissues, with special preference for the endometrium and tubes. The dependent portion of the pelvic peritoneum also becomes involved. There may be latent gonorrhœa that is without acute stage, and insidious in its development. Later, this may become an ascending gonorrhœa with its adverse consequences. It is possible to cure the infectious disease itself, but uterine catarrh and adhesions remain, starting up morbid processes at each menstrual epoch. In regard to accidents connected with the puerperal state, the author does not consider gonorrhœa as important a factor as Saegener does. In the acute stage applications of tannin and iodoform to the vaginal mucous membrane are recommended, and injections of bichloride of mercury, one part to one thousand. Cauterizations of the cervix with fuming nitric acid can also be employed, but intra-uterine medication is to be avoided. In the later stage of infiltrations, adhesions, and cicatrixes that cause pain, massage according to the Thure-Brandt method is of great value, together with the intra-uterine galvano-caustic. Observations based upon one hundred cases lead to the belief that removal of the tubes will always result in almost permanent freedom from pain. These cases have to be watched constantly after the operation, to insure the prophylaxis of ascending gonorrhœa.

Angiokeratoma.—Pringle, in *Monatsh. für prakt. Dermatol.*, xiii., 11 and 12, describes this dermatosis. It consists of small vascular tumors of which the epidermis is much thinned. These vascular tumors occur in the back of the hands and feet in subjects who suffer from chilblains. The affection has been described by M. Dubreuil as "telangiectasic warts." Mibelli gave it its present name. Microscopic examination reveals hyperplasia of the epidermis, together with vascular dilatations in the inflamed papillary layer. There is considerable hypertrophy of the Malpighian bodies. Angiokeratoma can be cured in a few weeks by electrolysis.

Influence of Small-pox on Menstruation, Pregnancy, and Lactation.—Before the *Société centrale de Médecine du Nord*, June 24, 1892, observations of thirty cases of small-pox in women were reported. In five wet-nurses there were five instances of suppression of milk, in two only transient; among six pregnant women there were three abortions, one premature birth, three still-born children, and the death of three mothers. Among nineteen women and girls there were no menstrual disturbances in ten light cases; in three there was metrorrhagia, followed by death in two instances; in four, menstruation was notably hastened, and in two retarded. The small-pox poison, and not the fever, caused these anomalies. They were severe in proportion to the extent of the eruption.

Alkalinity of Blood in Disease.—In the *Revue des Sciences Méd.*, 1892, p. 444, there is a statement to the effect that in general the alkalinity of blood is diminished in proportion to the decrease in number of red blood-globules, in richness of hæmoglobin, and in specific gravity. In pernicious anæmia alkalinity is lessened, but not in chlorosis. It is greatly reduced in leucæmia, diabetes, uræmia, cancer, cachectic states, pseudo-leucæmia, acid poisoning, and fevers of marked hypersthenia. Alkalinity is normally less in women and children than in men.

Psychology of Artists.—A study of artists from the scientific point of view, by Lucien Auréat, is an interesting little volume of the contemporary philosophy series. Brilliant exceptions to the contrary notwithstanding, artists in the main are sensational creatures, with the analytic and synthetic mind, intelligent but not intellectual. The portion of the book devoted to the pathology of painters, gives a striking account of the special infirmities and miseries of genius.

Treatment of Granular Ophthalmia by Pyroctanine.—Legros, in the *Presse Médicale Belge*, June 5, 1892, gives some interesting results of pyroctanine in granular conditions. Old ideas of treating the eye are rapidly giving way to surgical procedures, and these have definite disadvantages. Curetting of granulations, crushing, or expressing them, as done by Knapp and Noyes, of New York, necessitate local or general anæsthetics, and are measures not entirely free from troublesome complications, and do not always give good results. The author inclines, with Wecker, to the belief that treatment directed primarily to the destruction of the granulation itself is reprehensible, and that it is far better to attempt to destroy the supposed specific microbe that is lodged in the infiltrated tissue. Observations made by Valude, Vignal, and Gallamaerts, upon the power of diffusion of pyroctanine, gave to the author the idea of employing this agent in the Ophthalmic Institute of Brussels. Results were most satisfactory, the methyl-violet effecting a cure when used in relatively large doses, two grammes in sixty-five of water. There are no counter-indications for its use. At the same time, it is wiser to employ smaller doses when serious ulcers of the cornea are present. The inconveniences of this method are the following: rather tedious duration of treatment, staining power of the drug, and purplish discoloration of the cornea that persists for some time.

Solar Eczema.—Walters, of Bonn, in *Arch für Dermatologie und Syphilis*, April 15, 1892, notes a case of this kind in a middle-aged woman of excellent health, who, after exposure to the direct rays of the sun one warm spring day, experienced tumefaction of the face and severe outbreak of eczema. These symptoms were also present on the dorsal surface of the hands and forearms. In autumn and winter the sun had no pernicious effect; but in spring eczema appeared again. Wearing a veil had no hindering influence, the disease returning regularly with warm weather. Treatment would effect a transient cessation of symptoms that invariably reappeared upon exposure to the sun for a half-hour. Antiseptic gauze saturated with bichromate of potassium, originally suggested by Veiel, and worn as a veil, produced the happiest results, rendering afternoon sunshine harmless. Later, it was discovered that a green veil proved a better protection for the skin. As chemical rays are not absorbed by green, the conclusion was that caloric rays are alone responsible for solar eczema.

Clinical Department.

SCARLET FEVER TREATED WITH ANTIFEBRINE.

By HARRIET E. GARRISON, M.D.,

DIXON, ILL.

For more than two years I have treated all my cases of scarlet fever with antifebrine, and have been fully satisfied with the results obtained.

I first saw my last case on June 2, 1892. Hilda L——, aged eight years, had taken part with her schoolmates, on May 30th, in the memorial exercises. The day was wet and the children walked a long distance. The next day she was too tired to go to school. On June 1st, toward evening, she developed fever, sore throat, with nausea and vomiting; continued sick all night; but as there were no reported cases of scarlet fever in town the parents were not alarmed.

On June 2d I was called at 7 A.M. The face and extremities were pale, the body covered with a rash of a dark yellowish-red color; tongue covered with a white coating, excepting the tip, which was a bright red, with slightly enlarged papillæ. The pharynx presented the appearance of dark-red velvet; the tonsils were enlarged, and near the centre was a patch of pseudo-membrane; the submaxillary glands were swollen; deglutition painful; bowels constipated; urine scanty, dark-colored, and loaded with phosphates; temperature in axilla, 103° F.; pulse, 180, small and thready. She was still nauseated, and accordingly I immediately gave a few drops of aromatic spirit of ammonia, followed by calomel, 0.1 gm., sodium bicarbonate, 0.2 gm. In ten minutes this was to be followed by antifebrine, 0.1 gm., to be repeated every two hours until the skin was moist and cool. I directed the mother to recall me by telephone if the child was no better by 4 P.M.

June 3, 10 A.M.—Had taken no medicine since 10 P.M. The mother said the child had felt better before 4 P.M., perspired freely, and slept well during the night When I saw her she complained of no distress but a severe frontal headache. Face flushed purple; more swelling in the glands; temperature, 104° F.; pulse, 140, of good volume; bowels open; urine free and natural. The rash appeared on the extremities of a brighter scarlet than on the body. The other symptoms were unchanged. I gave antifebrine, 0.2 gm., with sodium bicarbonate, 0.2 gm., every four hours, to be continued until my next visit unless the hands or feet became cold.

On June 4th the symptoms were all better.

On June 5th the throat symptoms became temporarily worse, but were better the following day. The pseudo-membranous spot on the tonsil had never enlarged, and now looked dry and shrivelled. The temperature and pulse were normal.

My experience with antifebrine has been limited to sixteen well-marked cases. The first was an isolated case in the country, for which, without seeing the patient, I gave antifebrine under the supposition, from the father's statement, that it was follicular angina. This disease was very common at that time, and for it I had used the antifebrine freely, as it would control the angina in from two to four hours. Soon after taking the antifebrine the rash came out, but the patient was so well that I was not called until a younger child was attacked. Her temperature was 103° F. at my first visit, but when I called the next morning it was 101° F. She was well broken out with rash, and felt so well that I made no more visits. The mother reported her as well in less than two weeks.

My next cases were in the family of the Baptist minister, where there were six boys. These boys developed angina with the least exposure. One evening the father came for "some throat-powders for Johnny." The next evening, "Lee needs some powders, Johnny is well." At noon next day I was called to see Lee, aged seven years, and found him well broken out with the rash of scarlatina; temperature, 102° F. The case was not marked except by severe angina, pain in the ears, and swelling of the submaxillary glands, which I have since attributed to giving the antifebrine in too small doses. Two of the other boys, of eleven and sixteen years, had mild attacks. They were isolated with Lee at the first symptoms, and two of the family escaped. This was during what for our town was a severe epidemic. As far as ascertainable from defective reports there were forty cases, with four deaths. Of these I treated seven, without any mortality or sequelæ. In one family one child died, and I was called to treat the other for neuritis of the lower extremities, and the servant-girl, who at this time was sick with the fever. The child and girl made good recoveries. Johnny, who took the antifebrine for angina, is not included in these cases, as I saw no symptoms of scarlet fever after I was called, although until this time he and Lee were room-mates.

My conclusions from these cases are that antifebrine in scarlatina relieves the disagreeable symptoms, as pain and restlessness, and makes the patient comfortable. It shortens the duration of the disease. All my patients have been out of doors in two weeks, and the majority in ten days, after the beginning of the fever. It prevents sequelæ. In no case after using the antifebrine have the patients had any nephritis. Before combining sodium bicarbonate with it I occasionally found a case where the urine was not voided sufficiently often, but since then I have had no trouble. My first case had tenderness, with pain and weakness of the muscles in the lower limbs when I first saw him, three days from the onset of the fever. He had taken no antifebrine since the first day. A dose of antifebrine gave quick relief, and the pain did not return. This is the only symptom of neuritis in any of my cases. The third and sixth cases had severe pain in the ears, which increased doses of antifebrine, combined with hot applications, quickly relieved. In no cases have there been any abscesses in the ears or glands, or any discharges from ears or nose. Case six had every opportunity to develop sequelæ, as when I called at the house the tenth day after the fever appeared, not finding her in bed as I expected, upon asking for her she was brought in from out-of-doors, where she had been playing in a tub of ice-water. Desquamation was not yet completed.

It is best to begin the treatment as early as possible, but it will also be of benefit later on. In my twelfth case the child had been under the care of another physician four days, and the parents said it was growing worse steadily. As the physician had not made his regular call, and they were out of medicine, I was called in while attending a case in the same locality. The temperature was 103° F.; pulse, 160. As the child felt so much better after taking the antifebrine I was asked to keep charge of the case. The second day the fever was controlled, and the child made a quick recovery.

The first dose of antifebrine, if sufficiently large, produces a feeling of rest and the child lies quiet. My favorite way of administering it is to drop the powder into a tea-cup and pour in sufficient boiling water to dissolve it. Then have the child take it in small sips as hot as possible. In some cases I have used acetanalid pills, two and one-half grains; but where the angina is severe the solution makes a soothing application to the throat.

One of the benefits which I have frequently noted in my cases is the improvement in the quality of the pulse after the antifebrine is administered. Even where there is no lowering of the temperature there is an increase of volume and lowering of the pulse-rate. I have attributed this to its effect upon the nervous system.

In what manner the beneficial results are obtained, whether they are wholly due to the antipyretic and sedative action, or whether there is some specific action on the scarlet-fever poison, my observations have not yet determined.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, October 22, 1892.

THE DISEASES AND ACCIDENTS OF GREAT CROWDS.

THE medical history of the great Columbian celebration, which produced so much enthusiasm in this city last week, deserves some attention, and if it could be completely written would prove most interesting. There were probably four hundred thousand or five hundred thousand visitors during the week and perhaps a quarter of a million persons crowded the streets along which the parades were held. It is estimated that two hundred persons were more or less hurt or taken ill. The census as gathered by newspaper reporters from the police reports and hospitals makes the number about one hundred. Our readers will be interested in the list, as showing the accidents and diseases of great crowds. It is as follows:

Fainting, 35; hysterical seizures, 3; epileptic fits, 11; sprains, 3; run over, 3; fractures, 10—1 of the arm, 2 of the skull, 7 of the legs; falls, 11; cramps, 1; dislocation, 1; burned, mortally, 1; struck by a brick, 1; "taken sick," 13. Total, 94.

This shows that fainting is the most frequent pathological phenomenon, that crowds are bad for epileptics, that falls and fractures are numerous, and that delicate people are liable to be "taken sick." On the whole, the record is not a bad one, considering the enormous congregation of people. The reports also show that the sick and injured were promptly and efficiently cared for; and our much abused ambulance service evidently did yeoman's duty on the occasion.

VIVISECTION AND FOX KILLING.

OUR esteemed contemporary *Life* touches most of the events, customs, and manners of the day with a delicate satire in which there is so much good-humor that none can take offence. But it is, we think, a little embittered in its criticisms of the medical profession. We do not recall that it has ever spoken kindly of any physician, except Dr. Jenkins. It was recently both savage and unjust in its comments on certain physiological experiments conducted by a Philadelphia physician. These experiments were characterized as wantonly cruel and useless. There was no foundation for this opinion; and, in fact, we believe just the opposite was true.

Not far from this town there is a club whose business it is, about twice a month, to set free a tame fox, and then to chase it to death with dogs. We are not prepared to say that this is cruel and useless; but we submit that on the face of it such performances appear to be a thousand-fold more brutal than experiments upon the nerves of anæsthetized rabbits, done by trained hands for the purpose of establishing new truths in biology, yet the worrying to death of tame foxes has never excited anything but gentle raillery from the sensitive minds of the gentlemen who write the paragraphs of *Life*.

THE MEDICAL HISTORY OF COLUMBUS.

IT is unfortunate that in the great amount of literature recently put forth concerning Columbus one can find so little regarding the great discoverer's personality. His character and much of his career are still surrounded with a good deal of mystery. It is not to be wondered at, therefore, that the knowledge of his personal characteristics is so incomplete. Columbus is said to have been tall, very strong physically, and to have had red hair, blue eyes, and a ruddy complexion. He married rather young, but later in life formed irregular relations with a lady who bore him a son. He must have been a man of great vitality, and was probably a good liver when he had the opportunity, for he suffered many years from the gout and died finally from that disease. Like most men of powerful physique, and great ambition and energy of character, he probably indulged himself freely, or at least neglected to be prudent of his health. His exposures and privations do not seem to have been altogether the cause of his early physical prostration, for though he contracted "fevers," it is gout, we are told, which kept him an invalid and finally killed him at the comparatively early age of sixty. It is useless to moralize on what might have been if Columbus had been more ascetic; but no doubt the failure of his health had much to do with the neglect into which he fell before he died. If Columbus had retained the vigor of his middle life he would have made things so uncomfortable for his enemies that they would have been forced to give him justice.

TOBACCO AND THE TOBACCO HABIT.

AN article by Jules Richard upon this subject appears in English dress in the *Popular Science Monthly* for September. Tobacco-leaves contain principles common to all vegetable substances, such as starch, sugar, organic acids, salts, etc., and a peculiar alkaloid to which the plant owes its special qualities, called nicotine. Among the volatile principles that pass into the smoke along with nicotine are hydrocyanic acid and carbonic oxide. Of these, a notable amount is absorbed by rapid smokers swallowing this smoke, the gas passing into the circulation. These facts go far to explain the accidents that sometimes occur after hours passed in a medium saturated with tobacco, and even without smoking; and also explain the phenomena of intoxication produced by eating food left for a long time in similarly vitiated air. The decoction of tobacco destroys life in a time short in proportion to the strength of the dose. Tobacco may also poison through the lungs and through the skin. Smoking, which has had many imaginary ills laid to its door, is

really responsible for attacks of suffocation, like angina pectoris, for nicotine amblyopia, for granular pharyngitis, for a special form of asthma, and for epithelioma in the predisposed. Nearly all excessive smokers are dyspeptics. Smoking is bad for everybody, especially for women and children. At the same time, why paint it blacker than it is? Tobacco has never led the reason astray, destroyed the will, or perverted sensibility. The most hardened smoker enjoys perfect clearness of mind. Then the habit of smoking, unlike alcoholism and morphinomania, can be broken up permanently. Tobacco has none of the seductions and dangers of opium and hashish, of ether, chloral, and alcohol. Its action on the nervous system is weak and wholly especial. It does not put to sleep, but it calms and mollifies the sensibility of the organs. It causes an agreeable torpor, during which thought continues lucid and the capacity for work undiminished. Such is the attraction that it exercises, and which causes it to be sought for by so many thinkers and students.

THE TREATMENT OF GOITRE.

In the presence of so much conflicting testimony concerning the merits of the various methods of treating goitre, one naturally hesitates in making choice. To be sure, we must take into consideration whether the growth be parenchymatous or cystic, simple or exophthalmic, recent or of long standing. The plan of treatment then to be adopted will be either by internal remedies, external applications, interstitial injections, electricity, or operation. Possibly some of these methods may be combined. To instance two widely separated methods, geographical as well as therapeutic: Dr. Upendra Nath Sen writes in the *Indian Medical Gazette*, March, 1892, that at Mymensing it is an every-day occurrence to treat half a dozen cases, since half the population is affected. This great prevalence he attributes to the water of the Jamuna River. His treatment consists in the outward application of biniodide of mercury ointment, and the secret of success lies in the fact that "the patient must be kept facing toward the East sun at least for two hours, when the ointment will be absorbed." The cure is more rapid if tincture of iron be given internally at the same time.

Dr. Cline, of Woodstock, Va., states that he has "been surprised just twenty-two times in the cure of goitre." Tincture of iodine is used externally, while corydalis and iodide of potassium are given by the mouth. Dr. O'Reilly reports in the *Lancet*, April 2, 1892, success in reducing the size of a goitre, estimated to weigh six pounds, by the injection of a solution of perchloride of mercury alternating with one of iodine and one of permanganate of potash. When the tumor was reduced to about one-third its natural size and had become hard, it was removed by operation. Dr. Auerbach advises interstitial injections of osmic acid followed by massage for fifteen minutes, while iodine is given internally.

Dr. Kapper has reported marked diminution in the size of the enlargement in soft thyroid tumors, following injections of iodoform emulsion, according to Mosetig's plan.

In the simple goitre which occurs in pregnancy, as noted by Lawson Tait and others, there is usually a decrease in the size of the growth, or indeed it may wholly disappear after delivery; but cases have been observed where this fortunate cure did not occur, and an instance has just been recorded by Dr. Joffroy, where there was an increase with succeeding pregnancies and finally all the symptoms of exophthalmos appeared. Dr. Bally's investigations of seventy-seven cases operated upon at Socin's clinic, lead to the conclusion that intra-glandular enucleation is feasible in most cases, is not attended by dangerous hemorrhages, nor followed by paralysis of the vocal cords due to injury of the nerves; while, as regards recurrence, it gives as favorable results as those offered by partial extirpation, and the operation is not followed by any disagreeable consequences such as tetany or cachexia. Fortunately, goitre is not very common in the United States, but when, as was recently noted in the RECORD, no less than four hundred and twenty thousand persons suffer from the disease in thirty departments of France alone, the question of treatment becomes a very important one.

DOES MERCURIAL TREMOR EXIST?

THE *Journal des Connaissances Médicales*, July 7, 1892, publishes an interesting lecture recently given by Charcot at the Salpêtrière, and reported by Paul Blocq. Three cases of intention-tremor were presented to the class, one due to multiple sclerosis, the others to what is usually supposed to be mercurial poisoning. Mercury has had a bad name from antiquity down, and has been credited with causing numerous ills. To it are attributed various physical disturbances among fur-workers, hatters, mirror-makers, and gilders on wood. Mercury has been accused of remaining in the tissues, notably in bone, whether introduced by the mouth, lungs, or absorbed by the skin; and, according to popular belief, an autopsy would reveal the shining "half-metal" making bright lines or dots in osseous structures. Yet Virchow has never found traces of this popular cause of terror in any human bones. And mercurial tremor? While frequent among those whose profession, so to speak, has poisoned them, there are no records among syphilographers concerning tremor as the result of taking mercury. In shops where mercury is used, seven or eight years of service generally elapse before this symptom appears. When it shows itself in one particular individual, the experienced foreman promptly dismisses the victim, knowing well how rapidly others will be attacked unless this extreme measure is adopted. Charcot concludes that there is no such thing as mercurial tremor, and that the intention-tremor, said to be due to poisoning by mercury, is in reality hysterical, occurring in persons who have developed, or possibly originated, the hysterical state through close confinement, long hours, unhygienic surroundings, and the over-exercise of limited faculties. Dutil has made a special study of hysterical tremor, visiting shops and making examinations of five cases of mercurial tremor, so called, that were found there. In three there were hemianæsthesia, hysterogenic zones, and hysterical attacks, the latter often the precursor of tremor. With hysterical stigmata, as corroboratory evidence, the diagnosis of such cases is plain. And when classic stigmata are absent? Tremor itself is a stigma. There is a mono-symptomatic hysteria, as well as other forms. In tonic hysterias, in which some

poison is the predisposing cause, the nature of the agent seems to exercise some special influence upon its particular kind of manifestation. Lead gives chiefly anæsthesias and paralyses; alcoholism, convulsive crises; and mercury, in particular, this rare form of neurosis, tremor. This newer view of mercurial tremor alters routine treatment. Iodine and vapor baths give way to mechanical tonics—as the douche, shower, and pack—to gymnastics and massage, and to nervine tonics.

CAUSES OF BLINDNESS.

In Trousseau's new book, "The Hygiene of the Eye," the author gives certain statistics based upon causes operating in the 627 cases of blindness that have appeared at his clinic during the past ten years. The most frequent causes of blindness are optic atrophy and purulent ophthalmia. Then come in descending scale irido-choroiditis, glaucoma, traumatism, affections of the cornea, detachment of the retina, trachoma, pigmentary retinitis, chorio-retinitis, sympathetic ophthalmia, myopic sclero-choroiditis, congenital cataract, buphthalmia, optic neuritis, and staphyloma. Nearly one-half of these 627 blind persons had been attacked by some curable disease, and lost their sight unnecessarily. With proper medical care they could have remained useful human beings, instead of becoming useless and a burden to their friends.

ACUTE FEBRILE STERCOREMIA.

In the *Revue Générale de Clinique et de Thérapeutique*, No. 34, 1891, Duclos describes an acute specific fever, due to reabsorption of putrid fecal matters, and accompanied by symptoms of most serious poisoning. It takes the form of a grave attack of intestinal ulceration of the general adynamic type, or may appear as pernicious intermittent fever endangering life. Differential diagnosis can be made with care; and in spite of the intensity and gravity of the symptoms, the length of the disease, etc., the author has only known one death to occur. Drugs necessary are purgatives, intestinal disinfectants, and large doses of quinine.

REGIMEN IN BRIGHT'S DISEASE.

A recent communication from Dujardin-Beaumetz to the French Academy of Medicine states that in chronic nephritis the quantity of albumin excreted is of secondary importance. In point of prognosis the permeability and power of elimination of the kidney are of chief moment, and upon these alone can prognosis and treatment be based. The first thing to be done is to facilitate the elimination of toxines, and to lessen their production as far as possible. Elimination is aided by diuretics, purgatives, and stimulation of the functions of the skin. Proper diet and intestinal antisepsis lessen the production of toxines. Benzoate of naphthol is the best intestinal antiseptic, and a vegetable diet is best suited to sufferers from chronic nephritis. Fish, shell-fish, and fermented milk rapidly produce toxic ptomaïnes and are, for this reason, to be strictly avoided. In a general way, it may be said that meat, especially game, and all kinds of preparations of pork, salaisons, fish, shell-fish, and old cheese are injurious. To this list may be added alcohol, which irritates the kidney and diminishes its power of elimination. Vegetable diet includes milk and its preparations, eggs, cereals, fresh vegetables, and fruit. In recent German discussions some exception has been taken to eggs, not on the ground this time that they increase albumin, but because they augment the amount of retained urea. The question is: Can uræmia be prevented by abstinence from nitrogenous food? The answer is negative, in spite of the fact that non-nitrogenous diet is often advantageous in acute nephritis, though useless in chronic disease of the kidney. Dujardin-Beaumetz believes that this vegetable, or rather non-meat, diet will greatly prolong life, and that it should be earnestly recommended in all cases of Bright's disease.

News of the Week.

Iowa Public Health Association.—The second annual meeting of the Iowa Public Health Association will be held in Des Moines, in the rooms of the Y. M. C. A., October 27th and 28th, beginning at 10 A.M. of the 27th. An interesting programme has been provided, and the occasion promises to be one of great interest.

The Success of Quarantine in New York.—Representatives of fifteen lines, forming the Transatlantic Steamship Association, met at 19 Broadway, and adopted these resolutions:

Whereas, Dr. William T. Jenkins, Health Officer of the port of New York, and his staff, have, in our opinion, by their energy and devotion to duty averted an epidemic of Asiatic cholera that threatened not alone this port and city of New York, but also the entire country; and

Whereas, We consider the work of quarantine was and is conducted with a view to the least possible interference with business interests and travel, so as not to inconsistently obstruct or injure commerce; and

Whereas, We consider the different shipping interests of this port have been treated with impartial fairness; and

Whereas, The Hon. Charles Foster, Secretary of the Treasury, and the officers of the National Government acting under his direction, aided in this noble work; be it therefore

Resolved, That the hearty commendation of this Association be, and is hereby, given to Dr. William T. Jenkins and his staff, and to the Hon. Charles Foster, Secretary of the Treasury.

From July 31st until October 21st 1,120 vessels passed through Quarantine, carrying 96,344 persons, who were all examined by the Health Officer and his corps of assistants. Of this great number of persons, 20,187 were first cabin passengers, 16,145 second class, 19,270 steerage passengers, and 40,742 officers and crews.

American Electro-therapeutic Association.—At the recent meeting of the American Electro-therapeutic Association, the following officers were elected for 1893: *President*, Dr. Augustin H. Goelet, of New York; *First Vice-President*, Dr. William F. Hutchinson, of Providence, R. I.; *Second Vice-President*, Dr. W. J. Herdman, of Ann Arbor, Mich.; *Secretary*, Dr. M. A. Cleaves, of New York; *Treasurer*, Dr. R. J. Nunn, of Savannah,

Ga.; *Executive Committee*, Dr. W. J. Morton, of New York; Dr. G. Betton Massey, of Philadelphia; Dr. Robert Newman, of New York; Dr. Charles H. Dickson, of Toronto, Canada; Dr. J. H. Kellogg, of Battle Creek, Mich. Next place of meeting, Philadelphia, on Tuesday following meeting of Pan American Congress.

A Very Exciting Controversy over Vivisection has been going on in the English press. It has had a curious and interesting result. On October 15th the *Times* published a letter signed jointly by Sir Andrew Clark, Sir James Paget, Dr. Samuel Wilks, and Dr. George Humphrey, four of the recognized leaders of the profession. They declare that they will say nothing more about the subject in public print for these terse reasons: "First, after full consideration, we are satisfied that the scientific aspect of this question cannot receive adequate and just treatment in the columns of a newspaper. Second, because it is hardly possible for us to name any progress of importance in medicine, surgery, or midwifery which has not been due to or promoted by this method of inquiry."

Numerous Complaints Against the Female Specialty Man.—Numerous complaints are being made against the man who continues to send by mail his cheap advertising cards to physicians here and elsewhere. His impertinent persistence passeth all understanding. We wonder if the County Society can suppress the nuisance.

Some Advice from the Ancient Hindus.—The *Charak-Savuhita* says: "The use of perfumes and garlands conduces to virility, fragrance (of the body), longevity, and agreeableness. It affords nourishment and strength, promotes cheerfulness, and dispels distress and ill-luck. The wearing of jewels and ornaments conduces to respectability; it is auspicious and promotes longevity and beauty. It prevents all kinds of misfortune, confers cheerfulness and agreeableness, and enhances vitality. The practice of (washing and) always keeping clean the two feet and the outlets for the passage of excreta and urine, contributes to strengthen the intellectual powers, aids purity, promotes longevity, and destroys distress and ill-luck. The paring of nails and cropping and combing of hair, beard, and mustache, promote nourishment, respectability, longevity, purity, and beauty."

Prize Essays of the Medical Temperance Association.—The American Medical Temperance Association, through the kindness of J. H. Kellogg, M.D., of Battle Creek, Mich., offers the following prizes: 1st. One hundred dollars for the best essay "On the Physical Action of Alcohol, Based on Original Research and Experiment." 2d. One hundred dollars for the best essay "On the Non-alcoholic Treatment of Disease." These essays must be sent to the Secretary of the Committee, Dr. Crothers, Hartford, Conn., on or before May 1, 1893. They should be in type-writing, with the author's name in a sealed envelope, with motto to distinguish it. The report of the Committee will be announced at the annual meeting at Milwaukee, Wis., in June, 1893, and the successful essays read. These essays will be the property of the Association, and will be published at the discretion of the Committee. All essays are to be scientific, and without restrictions as to length, and limited to physicians of this country.

Reviews and Notices of Books.

A Practical Treatise on Diseases of the Skin. By John V. Shoemaker, A.M., M.D., Professor of Skin and Venereal Diseases in the Medico-chirurgical College and Hospital of Philadelphia, etc. Second Edition. 8vo, pp. 878. New York: D. Appleton & Co. 1892.

The second edition of this work has received the benefit of the author's four years additional experience since the original was offered to the public. Important advances have been made in several directions during the interval, which are reflected in the pages. This is especially noticeable in those diseases which have received bacteriological investigation. Electricity as a remedial agent has been treated of in a newly added special section, and the subjects of leprosy and syphilis have received additions from recent literature. All that pertains to dermatology has the imprint of having been written from the standpoint of an active general practitioner. Much attention has been given to treatment, and the author's fondness for combinations of remedies is reflected in over a hundred pages of formulæ, besides those scattered through the text. Forty-five pages of these prescriptions constitute a new formulary to the present edition, which being arranged alphabetically, according to diseases, offers a means of ready reference. The work is illustrated with a number of colored plates taken from nature, and has a very complete index.

Book on the Physician Himself and Things that Concern His Reputation and Success. By D. W. Cathell, M.D., Baltimore, Md. Tenth Edition. 8vo, pp. 335. Philadelphia and London: The F. A. Davis Co. 1892.

The reputation of this book, as an ethical guide to the physician, is so well established that it is only necessary to say it has reached a tenth edition. We are not surprised at its success, and congratulate the conscientious author accordingly.

Transactions of the Medical Society of the State of New York. 1892. 8vo, pp. 540.

This volume is of the usual size and contents, which is to say that it contains the usual number and variety of articles from specialists from New York and elsewhere, and the usual paucity of articles of real value to the country practitioner, for whom the work is apparently more specially intended.

The American Text-book of Surgery for Practitioners and Students. By Charles H. Burnett, M.D., Phineas S. Conner, M.D., Frederic S. Dennis, William W. Keen, Charles B. Nancrede, M.D., Roswell Park, M.D., Lewis S. Pilcher, M.D., Nicholas Senn, M.D., Francis J. Shepard, M.D., L. A. Stimson, M.D., William Thomson, M.D., J. Collins Warren, M.D., and J. William White, M.D. Edited by William W. Keen, M.D., LL.D., and J. William White, M.D., Ph.D. 8vo, pp. 1205. Philadelphia: W. B. Saunders. 1892.

A striking feature of this work is that of anonymous authorship of articles. The authors, thirteen in number, although well-known men, have for some unexplained reason thought best to disclaim all individual responsibility for work on special subjects. Such a proceeding gives their writings a relative rather than positive value, and denies the reader the satisfaction of fixing his own estimate of authority upon particular sections. The editors have shown much judgment in the arrangement of the work, and the subjects are on the whole tersely and practically treated. Large and densely printed as is the work, there is a wonderful amount of material compressed between its covers. While this would be a strong recommendation of the value of the work to the general prac-

titioner, it is altogether too much for the student as a text-book during the college course.

The illustrations are numerous and varied, but of very unequal excellence. We have a wide range between the very good and the very bad. The major part of them, however, are original and, as far as many of them go, will doubtless serve the purpose of a student who has no opportunity perhaps of comparing their excellence with similar ones in standard treatises. Aside from these objections we have nothing but praise for the work. It goes over the ground of general surgery differently and better than most compendiums of its class, and will doubtless earn for itself an enviable position as a standard treatise. We regret that the publishers have classed it strictly as a subscription book; as such it is necessarily made expensive for the student, who must purchase it through agents and consequently without the usual discounts allowed to him.

Regional Anatomy in Its Relation to Medicine and Surgery. By George McClellan, M.D., Lecturer on Descriptive and Regional Anatomy at the Pennsylvania School of Anatomy; Professor of Anatomy in the Pennsylvania Academy of Fine Arts. etc. Vol. II. 4to, pp. 414. Philadelphia: J. B. Lippincott Co. 1892.

The expectations which the first volume of this admirable work encouraged have been fully realized in the second, which completes the work. It comprises all those regions in the lower half of the body, viz., the abdomen, groin, pelvis, perineum, hip, thigh, leg, and foot, as well as the back, lumbar, and gluteal regions. It contains forty-three admirable full-page plates of colored photographs, taken by the author from his own dissections, expressly designed and prepared for this work, and colored by him after nature. These plates embrace larger or smaller illustrations, which in the aggregate give the reader everything required in the way of ocular demonstration of every region of the body. The importance of this work is enhanced by the practical manner in which the several subjects are presented. The method is in many respects original, in that it gives not only the anatomical but the clinical aspects of the subject. It is, in fact, clinical anatomy for the physician as well as the surgeon. The plates are accurate and artistic, and bring the student face to face with actual dissections, made by an experienced teacher who fully appreciates the necessities of the student, and who successfully infuses instructive interest into what would otherwise be dry reading. The work needs only to be known to be properly valued.

Transactions of the Eighth Annual Meeting of the American Climatological Association (1891). Philadelphia: W. B. Saunders. 1892.

The volume is made up of the twenty-eight papers presented at the session held in Washington in September of last year. These are naturally upon topics of special interest to the students of diseases of the respiratory tract, and are all creditable contributions to medical literature. The Association is organized on a sensible basis, has an energetic membership, and has long since justified, by its good work, its existence.

Spondylolisthésis et Spondylizéme. Résumé de Recherches Littéraires et Personnelles depuis 1880 jus-qu'en 1892. Par le Dr. François Neugebauer (de Varsovie). Avec Introduction par le Professeur A. Charpentier. Paris: G. Steinheil. 1892.

This monograph was written by Dr. Neugebauer at the instance of Dr. Charpentier, and was originally intended to form one of the chapters in the latter's work on obstetrics. The essay grew constantly larger as the author went on, and finally it was found to be too voluminous to form part of the other treatise. An abstract of it was made for this purpose, and it was decided to publish the monograph itself in separate form. This subject of spondylolisthesis has been pretty carefully studied b Kilian, Herrgott, and others, but none has ever befor so thoroughly mastered it and produced so valuable treatise as Neugebauer. His work is founded upon th study of about fifty clinical cases, seen by himself an others, and of an equal number of museum specimen The subject is one of especial interest to the obstetricia and to the orthopedic surgeon, and the work before r will, it is safe to predict, be for a long time to come th standard treatise on this deformity.

Geographical Pathology. An Inquiry into the Ge graphical Distribution of Infectious and Climatic Di eases. By Andrew Davidson, M.D., F.R.C.P. Ed Late Visiting and Superintending Surgeon, Civil Ho pital, Mauritius. 2 vols., 8vo, pp. 1004. New York D. Appleton & Co.

The object of this work is to sketch the geographical di tribution of infectious and climatic diseases, and at th same time to trace the influence of temperature, rainfal altitude, and soil conditions on their prevalence, chara ter, and epidemic spread. The fulfilment of such a pu pose by the author is the highest praise that can be give for patient research and wide-spread study. The syste which he has adopted has enabled him to present th subject in a light which cannot fail to interest the phys cian, philosopher, naturalist, sanitarian, statesman, an general student. Indeed, any effort intended to stud the natural laws of disease on a comprehensive scale ca not fail of wide appreciation by a large class of though ful readers. To such this admirable work appeals wit striking force and novel interest. No work we have see has approached it in thoroughness of detail or compr hensiveness in design.

A Manual of Chemistry, Inorganic and Organic, wit an Introduction to the Study of Chemistry. B Arthur P. Luff, M.D., B. Sc. (Lond.), M.R.C.P.; Fe low of the Institute of Chemistry; Fellow of the Chem cal Society; Physician to Out-patients in St. Mary' Hospital and Lecturer on Medical Jurisprudence an Toxicological Chemistry (Late Demonstrator of Chem istry) in the Medical School; Examiner in Forensi Medicine to the University of London; Examiner i Public Health to the Royal College of Physicians London. Illustrated with thirty-six Engravings. Phi adelphia: Lea Brothers & Co. 1892.

This is one of the best text-books on chemistry for med cal students that we have ever seen. It is written b one who is a physician as well as a chemist, and who ur derstands how much of the latter science the student c medicine requires, and also how to present it to him in way to interest and attract instead of to repel. If all th text-books on chemistry put into the student's hands ha always been as practical and "easy" as this, ther would not be such a woful ignorance among physician of the merest elements of the subject as there is at th present day. But if the book before us is a sample o what the rising generation has to study from, we ma indulge in the certain hope that the medical man of th future will know a little of this most fascinating of a physical sciences.

The Essentials of Histology, Descriptive an Practical. For the Use of Students. By E. A Schäfer, F.R.S., Jodrell Professor of Physiology i University College, London; Editor of the Histolog ical Portion of Quain's "Anatomy." Third edition revised and enlarged. Illustrated by more than thre hundred Figures, many of which are new. Philadel phia: Lea Brothers & Co. 1892.

This is intended as a text-book for students pursuing course in class on histology, for which purpose it is wel adapted. It is divided into forty-five chapters or lessons beginning with the human blood-corpuscles and endin with a study of the organs of special sense. Each lesso

egins with brief directions for the preparation of speci-ens to be studied, after which the author gives a clear escription, supplemented by very good illustrations, of hat is to be seen under the microscope. An Appendix ontains directions for preparing and mounting speci-ens. A belated student or young practitioner whose stological education had been neglected might well sup-ly the deficiency by private study guided by this excel-nt manual.

. Handbook of Hygiene and Sanitary Science. By George Wilson, M.A., M.D., F.R.S. Edin., D.P.H. Camb., Fellow of the Chemical Society; Fellow of the Sanitary Institute of Great Britain; Medical Officer of Health for the Mid-Warwickshire Sanitary District; formerly Medical Officer H. M. Female Prison, Woking, and H. M. Convict Prison, Portsmouth. Seventh edition. Philadelphia: P. Blakiston, Son & Co. 1892.

his is a very convenient work for reference or study, nd is one with which any medical man who has to do at l with questions of public health cannot well afford to ispense. Especially will those who practise in the ountry or in small towns find the work of great assist-nce, for it is they who are more often called upon by ie community in times of public peril to advise con-erning measures of safety and protection from a threat-ning or actual epidemic. Indeed, all physicians should ave some knowledge of this most important subject. he author has practically rewritten the entire work for is edition, and has brought it thoroughly up to date. he chapters on "Ventilation," "Water and its Analysis," Communicable Diseases," and "Prevention and Disin-ction," are especially interesting to the practising phy-cian, though the entire work will well repay perusal. ext to the unrivalled work of Parkes, we know of no etter work on sanitary science than this of Dr. Wilson.

Diseases of the Stomach. By Dr. C. A. Ewald, Professor of Medicine in the University of Berlin. Authorized Translation (from the Second German Edition, with special Additions by the Author), by Morris Manges, A.M., M.D., Attending Physician to Mount Sinai Hospital Dispensary, New York, etc., with thirty Illustrations. New York: D. Appleton & Co. 1892.

his work represents Volume II., of Professor Ewald's Klinik der Verdanungskrankheiten." Volume I. is not ncluded, as it has recently been rendered into English y Dr. Saundby. The translator's work, which is of high erit, has been carefully read by the author, and addi-ons made thereto. Hence the volume is not merely a endering of the second German edition, but it practi-ally represents, from its containing the very latest in-estigations on this subject, the third German edition, hich is soon to appear.

To read this volume is to read the history of a very in-eresting development in modern medicine. Dyspepsia a term which can no longer be tolerated in exact clin-al work. It ranks with dyspnœa and dropsy as a symp-matic term only, and not as a pathological entity. s this differentiation Ewald has had an important share nd is to be ranked as one of the highest authorities. he present volume will be welcomed by all, especially hose to whom the original text has not been accessible.

The first two chapters are devoted to "Methods of Examination," and are written with Teutonic thorough-ess. Physical examination comprises inspection, pal-ation, auscultation, and mensuration. Next comes the nalysis of the chemical, absorptive, and motor functions f the stomach. Under the latter are described the use f the tube, expression of gastric contents, salol test or motor activity, etc.

We note in passing that Ewald prefers tubes of differ-nt thicknesses with the lower end open, with one large, tteral fenestrum low down, and a number of smaller penings about the size of a large pin's head. He does not regard the use of such devices as Einhorn's "stomach-bucket" as at all necessary, except in rare instances. He believes that the stomach contents can be obtained in sufficient quantity for examination by the passage of the tube and abdominal pressure.

The sections on the chemical side of diagnosis are complete and easily understood. They are not at all beyond the comprehension of the average intelligent physician. Regarding the normal acidity of the viscus, it might possibly be insisted on with more emphasis that an acidity which is normal in one individual may be hyperacidity in another. There is difficulty in this respect in establishing a normal.

Following this introductory part of the volume are chapters on "Cardiac and Pyloric Strictures and Contraction," "Dilatation," "Ulcer," "Cancer," and the "Inflammatory Diseases." Three chapters are devoted to "Neurosis of the Stomach," and one on "The Correlation of the Diseases of the Stomach to those of Other Organs." "The Practical Value of the Modern Chemical Tests," completes the book.

It is perhaps in the latter that the average reader finds most interest. Such a chapter in a book on a highly specialized topic shows the gauge of a writer's mind. If it is narrow, all maladies will turn upon the condition of the particular organ or organs he treats. The genial Autocrat has remarked that "the specialist has but one fang with which to seize his prey, and that is a long and cruel canine." It is a matter of profound congratulation that in the present volume Ewald shows himself to be a man with a mind of broad gauge. He goes so far as to say that every physician ought to treat gastric maladies with intelligence and success.

In regard to the practical value of the modern chemical tests, Ewald says: "There are two great groups of results in the chemical examination of the gastric juice which differ from the normal. 1. The untimely occurrence of organic acids. 2. The changes in the gastric juice itself (*i.e.*, the secretion of hydrochloric acid, pepsin, and rennet), and the absorption and motility of the organ." The former is always characteristic of definite pathological conditions. These acids mean decomposition or fermentation referable to manifold causes. Regarding the second group it may be said that one class of diseases never causes increased HCl. This class is the one in which an extensive organic destruction or change in the secreting parenchyma has taken place. It includes carcinoma, chronic gastritis and its sequelæ, atrophy of the mucous membrane, and mucous degeneration of the gastric glands; possibly, also, certain chronic vascular lesions, *e.g.*, amyloid changes in the gastric vessels.

An increased secretion is always functional, a sign of irritation, but such over-production may, as the results from exhaustion following over-excitation, or, if attended by depression from the start, cause exactly the opposite condition. The diagnosis of cancer cannot be made merely from the absence of HCl.

We regard Ewald's work as one of the most important of the year. It is not meant to be a text-book, but is rather a course of lectures to practising physicians. As such it is characterized by a fundamental attention to pathology. It recognizes the limitations of therapeutics, and is enriched with a wealth of clinical experience.

Transactions of the Thirteenth Annual Meeting of the American Laryngological Association, Held in Washington, D. C., September, 1891. 8vo, pp. 166. New York: D. Appleton & Co.

This volume contains a number of interesting and instructive papers on subjects connected with laryngology. An idea of their scope and variety can be obtained from the following list: Removal of toy balloon from the trachea; thyrotomy in a child of eighteen months; on paralysis of external tensors of the vocal bands; the tonsils in health and disease; the use of pyoctanin as an

antiseptic in diseases of the upper air-passages; the treatment of the upper air-passages in asthma; nasal papillomata; nasal tuberculosis in a monkey; cyst of middle turbinated bone; diseases of the ethmoid cells; treatment of nasal myxomata; the upper air-passages in influenza; cicatricial contraction of larynx; intrinsic epithelioma of larynx; enlargement of epiglottis; surgical treatment of tubercular laryngitis; and relations of the mucous membrane of upper air-passages to constitutional conditions.

Cancer of the Mouth, Tongue, and Œsophagus; their Pathology, Symptoms, Diagnosis, and Treatment. By Frederic Bowreman Jessett, F.R.C.S. Eng. 8vo, pp. 177. London: Baillière, Tindall & Cox. 1892.

This book for its size contains a great deal of practical value to the operating surgeon. The different subjects are well treated, and the necessary operations in each region are well described. The work contains also a great amount of statistical material bearing upon some mooted points regarding results of different operations. There are several woodcuts illustrating some of the commoner plastic operations about the face.

The Manual of Obstetrics. By A. F. A. King, A.M., M.D., Professor of Obstetrics and Diseases of Women in the Medical Department of Columbian University, Washington, D. C. Fifth Edition. 12mo, pp. 438. Philadelphia: Lea Brothers & Co. 1892.

This now well-known manual has reached its fifth edition, and challenges criticism as one of the best of its kind.

Diseases of Women: a Manual of Non-surgical Gynecology. Designed especially for the use of students and general practitioners. By F. H. Davenport, A.B., M.D., Instructor in Gynecology, Harvard Medical School. Second Edition. 12mo, pp. 323. Philadelphia: Lea Brothers & Co. 1892.

We are pleased to note that this useful work has been properly appreciated, as is evidenced by the early appearance of a second edition. The author is a practical teacher, a perspicuous writer, and one who thoroughly understands what a student and practitioner may wish to know of ordinary and every-day safe gynecology. The illustrations are numerous and serve well their purpose.

Public Health Papers and Reports. Vol. XVII. 8vo, pp. 312. Concord, N. H.: Republican Press Association. 1892.

This volume, uniform with the preceding series, comprises the papers and reports of the Nineteenth Annual Meeting of the American Public Health Association, held at Kansas City, Mo., October, 1891. The subjects treated cover a wide range of thought, which, although consistent with the spirit and purpose of the Association, are open to the objection of presenting a striking variety. For instance, we have strung together, on the consistent rosary of hygiene, papers on empiricism, on rice culture, on diseases among chinch-bugs, on the necessity of bathing, on the heights and weights of children, the relations of plumbers and physicians, the prevention and treatment of rabies, and some hints on diphtheria in the Mexican highlands. They are all good papers, and of sufficient variety to suit any taste.

A Text-book of the Principles and Practice of Medicine, for the Use of Medical Students and Practitioners. By Henry M. Lyman, A.M., M.D., Professor of the Principles and Practice of Medicine in the Rush Medical College, Chicago. With one hundred and seventy Illustrations. Philadelphia: Lea Brothers & Co. 1892.

This is an excellent treatise on the practice of medicine, written by one who is not only familiar with his subject, but who has also learned, through practical experience in teaching, what are the needs of the student, and ho to present the facts to his mind in the most readily a similable form. Although the book contains over nin hundred pages, there has been no space wasted by us less historical essays, prolonged discussions on debatab topics, or "padding" of any kind. Each subject is take up in order, treated clearly but briefly, and dismisse when all has been said that need be said in order to giv the reader a clean-cut picture of the disease under di cussion. The mistake of giving too much space to th section on treatment has been avoided. The reader not confused by having presented to him a variety different methods among which he is left to choose th one most easy of execution, but the author describes th one which is, in his judgment, the best. This is as should be. What the student should be taught is the or most approved method of treatment, for he will hav plenty of time in his early days of practice to learn th views of others, and to choose for himself the plan treatment which may seem to him the best adapted t the occasional case that may fall into his hands.

We have spoken of the work as one for the studen and this because the author occupies so prominent position as a teacher, but we would not be understoo that it is adapted only for students. There is many practitioner of ten years or more standing, who has bee unable to follow the constant advances made in medic science, to whom this work will be of great use. H will find here each subject presented in its latest aspec and only such theories mentioned as have been generall accepted by the highest authorities.

As we have intimated before, Dr. Lyman's work is nc encyclopædic in character, and one who wishes to loo up a subject at his leisure and learn all there is to lear about it, should not look here. But the practical an busy man, who wants to ascertain in a short time all th necessary facts concerning the pathology or treatment any disease, will find here a safe and convenient guide.

Temperament, Disease, and Health. By Frenc Ensor Chadwick, Commander, U. S. N. New York G. P. Putnam's Sons. 1892.

We do not, as a rule, approve of works of this kin written by laymen, for they are generally written t support a fad or a theory, and medical facts are twiste and distorted, or else utterly ignored, in order to a tain the object aimed at. But we cannot say this co cerning Commander Chadwick's monograph. The a thor has a theory, it is true, but it is a theory that in th main does no violence to common sense or to scient fically proven facts. His object is to draw attention t the wonderful rapidity of change in the human body, an to the necessity which this entails of getting rid of th used-up matter that is thrown off from the skin. In othe words, he preaches the doctrine of cleanliness—a mos saving doctrine, and the one upon which man mus chiefly rely for his physical salvation. He carries h theory a little too far, however, in attributing such a larg share in the production of fatigue, after a day's work, t the presence of bacteria and waste products upon th skin. Fatigue, mental or bodily, is something mor than this, and cannot be entirely removed by a bath an change of clothing. The author is thoroughly well rea in the science of hygiene and preventive medicine, an his chapter on micro-organisms is a really admirabl presentation in abstract of the generally accepted bac teriological theories.

Ice-water.—A great deal is said about the danger c drinking iced water, with the thermometer at 97° F. may be well to say something about the danger of nc using it, about the great suffering without it, and th relief from employing it. Iced water, slowly drunk i moderate quantities, is not only a great boon to the ove heated and thirsty man, but it is a necessity in this sun mer climate.—*The Post-Graduate.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 6, 1892.

LFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

tic Brain Disease — Its Varieties, Diagnosis, and reatment — With Illustrative Cases.—DR. HERMAN NAPP read a paper on this subject. The gravity of the tension of disease of the ear to the brain had been appreciated by the profession at all times, but never before e present had it been studied in so systematic a manner, id yielded to conservative surgery such important triphs. All suppurative disease of the external auditory nal might occasionally prove fatal by involving the ain. The warning signal should be given as soon as eningeal irritation was noticed. This being the first ep to otic brain disease, he considered it, and passed ccessively to otic meningitis and suppuration, cerebral d cerebellar abscess, and sinus thrombosis—all of which illustrated by typical cases from his own experience. The chief symptoms of meningeal irritation were pertent headache, occasional nausea, vomiting, and dizziss, with moderate increase of temperature and acceleron of pulse; the latter depending more on the primary tic disease than on the meningeal involvement. Loss appetite and constipation were not characteristic. rcussion was either painless or painful only near the above and behind. The diagnosis between meningeal itation and real meningitis was very difficult.

The form of otic disease most likely to lead to cra-l complications was acute catarrhal suppurative otitis dia, due to pharyngitis, exposure during sea bathing, ., to measles, and scarlet fever. In 1878 he had put gether all cases of acute otitis coming under his prace the first ten years of his stay in New York—182—of ich 4 were fatal. Then he rarely punctured the drum, l never opened the mastoid. He thought now that o of the fatal cases of meningitis might possibly have n saved by opening the mastoid.

Of one of the first cases whose history he related, he d it was one of those of aural abscess, the large major- of which recovered, but some of them terminated ally, which might have been saved by operative interence. The rule to make an early and extensive inci- into the bulging membrana flaccida and the adjacent terior wall of the canal seemed a good one, and in this pect he had been, he said, more conservative and dila- than he ought to have been, or would be in the future. t was difficult to recognize when meningeal irritation l passed over into meningeal inflammation. As soon ersistent headache was followed by attacks of vomit- stupor, and marked rise of temperature, one should e warning and operate at once. Make a large paratesis, and if there was no subjective relief, open the stoid and penetrate the antrum into the attic. Even te cases of otitis might end fatally in a very short time, having reported one case which ended in death on the day; but usually they ran over a fortnight.

Referring to one of the fatal cases from cerebral comation, he said he thought it would have been correct tment to open the mastoid first, and not finding pus, reak the posterior wall of the meatus or enlarge the um into the attic; and not yet finding pus, to open the l above the ear. If no meningitis or extra-dural supation were then noticed, open the dura and incise the poro-sphenoidal lobe. It seemed that in this way the ection of pus might have been reached, but there was puzzling condition of the operator, who at every step he proceeding was confronted with the uncertainty of diagnosis.

here was a group of cases in which the pus in the , antrum, and mastoid cells had a tendency to break ugh the median wall of the mastoid. The pus might e its way outward and follow the sterno-mastoid muscle down the neck, or even to the anterior mediastinum. The author related one case in which he opened into the mastoid down to the lateral sinus, into the attic, also into the cranial cavity through the temporal bone, did not incise the brain, did not find pus. The patient died, and at autopsy there was found purulent phlebitis of the sinuses, and an abscess in the temporo-sphenoidal lobe which could have been reached through the opening he had made, and another in the cerebellum opposite the opening into the mastoid, which might also have been reached had he known its existence. Those were dangerous cases in which the outer table of the mastoid was healthy, and yet there were signs of severe brain disease.

One case was related in which he operated on the ear, searching for pus, and although the man had had otic disease, the cerebral inflammation proved to be tubercular, secondary to pulmonary phthisis.

A woman was presented, whose otic trouble had gone to the extent of producing the pyæmic hue, choke disk in both eyes, etc., but recovered after he had opened into the mastoid and antrum, finding a large quantity of thick pus in the antrum and pneumatic cells, and removing a great deal of diseased bone—the outer table having been found healthy

DR. LANDON CARTER GRAY said the paper added further evidence to the value of an early operation in cases of otitis complicated by symptoms of brain disease. He thought the author took rather a pessimistic view of the difficulties of cerebral diagnosis. All of the cases seemed to have shown that an early operation could have done no harm, and might have been of the greatest benefit. While it was true that it was often very difficult to make a diagnosis between simple meningeal irritation and meningeal inflammation, still in many cases by close observation it could be done. If there was trouble in the ear which affected the facial nerve it would involve the filaments conveying the sense of taste to the anterior portion of the tongue through the chorda tympani. If there was inflammation of the facial as it went off from the base of the brain, this sign would be wanting. There might be vertigo in inflammation of the ear, and also in inflammation at the base of the brain; but it was of a different type in the two cases. Besides, symptoms pointing to implication of other parts might be present in inflammation at the base of the brain. Dr. Gray alluded to the experiments on animals by Avalt, which had led that gentleman to speak of there being in the ear an auditory labyrinth and a tonus labyrinth. If these observations were confirmed on man, they might assist one in distinguishing between vertigo caused by implication of the ear, and that caused by implication of the base of the brain.

The more Dr. Gray had observed of cerebral surgery, the more astonished had he become at the immunity with which operations could be done under antiseptic precautions. We had not yet learned the limits of interference with the brain. In aural disease, if there were any doubt as to involvement of the brain, he certainly would feel that the mastoid cells should be cut down upon, that one should go deeper if necessary, and finally, instead of abandoning the case, lay bare the temporal lobe, and not hesitate even to use the exploring needle or blunt probe. Cranial surgery had given some brilliant results. Of one hundred and sixty-five operations for tumors, the percentage of recoveries had been as high as fifteen. We should go much more freely into the brain in the future in doubtful cases.

DR. BENJAMIN SACHS said the neurologist was not infrequently consulted as to the question whether, in a given case, there was brain disease complicating ear disease, and as to its location, or whether there might be tubercular disease or a tumor. He did not think the differential symptoms were as distinct as Dr. Gray had intimated, and in many cases it was impossible to say whether certain symptoms were due to ear disease or to cerebral disease. He thought involvement of the facial nerve was comparatively rare in the cases under dis-

cussion. The symptoms oftener resembled those of cerebellar tumor. The speaker mentioned a case of supposed cerebellar tumor in a boy, aged eight years, who was taken suddenly with vomiting, nausea, vertigo, dizziness, marked ataxia, slight optic neuritis. He gave an unfavorable prognosis, but one day a free discharge unexpectedly took place from the ear. He related another case, that of epilepsy in a boy who had otorrhœa a long time, the epilepsy developing after the discharge had ceased. The epileptic attacks were preceded by an aural or olfactory aura. At his suggestion Dr. Gerster operated on the mastoid, and the attacks ceased until the passage became again blocked; he then operated a second time, establishing permanent drainage through a silver tube, and there had been no attack for ten months. He had seen two cases recently, noted as otitis, due to nasal operations—a warning for operating rhinologists.

The surgeon should be allowed to interfere in aural disease much earlier than he was usually called upon, and if necessary, one should enter the cranial cavity.

Dr. Emil Gruening thought this subject was one which especially concerned the general practitioner, for otitis seen first by him and neglected, or treated badly, was likely to call for an operation on the mastoid. Boric acid powder, etc., was likely to be blown into the ear and the discharge be stopped, which was just the opposite of what the aurist sought. Peroxide of hydrogen was even worse than boric acid powder, thickening the pus, making it cheesy-like, so that it could not get out. As to operations upon the mastoid, he had done more in Mount Sinai the past two years than had been done in all the other hospitals in the city, and yet he could say that he had always operated later than he should, had he had opportunity, for he had found pus, or the bone softened. If surgeons would operate upon the mastoid in time, they would find the necessity for operating for complicating cerebral disease arise very rarely. When the brain was involved there was apt to be meningitis, abscess, and thrombosis; and he might add that the latter condition, thrombosis of the sinuses, occurred frequently. Its symptoms were usually well pronounced. He thought Dr. Knapp's operations had not been efficient enough. One should do more than open the mastoid and drain. The carious bone should be followed up, removed, and the opening be packed from the bottom with gauze.

Dr. F. E. D'Oench was glad to hear from the neurologists that operative interference in aural disease complicated by brain symptoms was considered at the present time a proper procedure. It had been his misfortune, the last three years, to see five fatal cases of brain disease complicating suppurative otitis. In four he thought there was no doubt of suppurative meningitis, while in one he believed there was a cerebral abscess which ruptured suddenly into the lateral ventricles. In the latter case the patient did well some days after an operation on the mastoid, went out of the hospital, then suddenly developed brain symptoms, strabismus, loss of consciousness, etc. He found nothing at the mastoid and cerebellum, laid bare the temporo-sphenoidal lobe; the brain bulged; he aspirated, withdrawing six ounces of fluid which was not exactly pus, but turbid, and believed to be from an abscess which had broken into the lateral ventricle. The strasbismus disappeared immediately, but the patient did not regain consciousness, and died twelve hours later.

Where dural inflammation occurred in connection with aural disease, ordinarily it was on the posterior surface of the petrous portion.

Dr. M. Allen Starr said he had had opportunity to see one of Dr. Knapp's cases in which a brain abscess was found, and a similar one in Boston, and they had impressed him strongly as to the difficulty of diagnosticating brain abscess in the vicinity of the ear. The neurologist knew about some portions of the brain, but when other unknown portions were affected by disease we had no means whatever of making a diagnosis. When abscess affected the lower temporal convolutions or the lateral lobes of the cerebellum, we had no means whatev of making a diagnosis. From this it followed that whe aural disease called for an operation it should be ma early, before it implicated the brain, as here there was t greatest difficulty in locating the abscess and determini where to operate.

Dr. T. R. Pooley's views were in accord with tho of Dr. Gruening. To this gentleman we were much i debted for the advance that had been made in the su gical treatment of aural inflammation. If his examp were copied more extensively, there would be fewer cas of complicating brain disease. Dr. Pooley related t case of a lad who had had chronic otorrhœa for yea He had had vertigo, nausea, and symptoms pointing cerebral disease, and when seen by the speaker there w diffuse swelling over the mastoid, the swelling extendi down the neck. His assistant operated, making a limit incision and evacuating pus, but when Dr. Pooley turned to the city the lad was still suffering from hea ache, vertigo, and had some fever. He enlarged t wound and cut down, exposing the dura over the late sinus. The relief was only temporary, and besides sym toms already mentioned, choke disk, motor paralys etc, developed, and the patient died. A neurologist h advised against an operation, being in doubt wheth there was cerebral abscess or meningitis, but leaning to t diagnosis of meningitis. The autopsy showed meningi and abscess in the anterior portion of the occipital lol with cerebral softening; also thrombosis of the late sinus, and extension of the inflammation to the jugu vein. An operation, it would be seen, might have reveal the abscess and have seemed a brilliant success, but t meningitis would, any way, have caused death.

Dr. Knapp called attention to the fact that ma craniotomies had been performed, that it had often be necessary to trephine in a number of places, and it w apparent that the difficulty was less in operating than diagnosis and localization. The remarks of Drs. Str and Sachs upon this point were, in his experience, corre In cranial thrombosis, however, the percentage of su cesses had been greater—seven cases, and four successf Thrombosis and subsequent pyæmia were not rare. I agreed with Dr. Gruening that a thorough operation w proper, but he did not believe in going to the extre at first, since if relief did not take place the opening cou be afterward extended. In his own cases his limited i cision, sufficient, however, to evacuate pus, had been ju tified by the result. In ladies, especially, it was not des able to leave too large an opening in the mastoid, as was disfiguring. Where the discharge could be ma abundant through the ear the majority of cases would g well without opening the abscess. He thought that the whole the subject was an exceedingly thankful or and merited further cultivation.

Dr. Gruening remarked that the operation which and Dr. D'Oench performed was not disfiguring.

The Cow as an Enemy of Mankind.—In a discussi on tuberculosis in Chicago, recently, Dr. Robinson sa that the death of babies who are fed by cow's milk is d to germs, and among these germs the tubercular bacill plays a *rôle*. He said that it appeared to him that t home of the tubercular germ is in the cow, and that t bovine family is where the bacillus of tuberculosis fin its native living-ground. He believed that man gets t tubercular germs from this animal. If the people wh have no cows are studied it will be found that they ha less tuberculosis. The people who use the milk of t reindeer, or the buffalo, or the goat will be found wi less tuberculosis than those who use the cow. The h tory of the association of man with the cow is, the speak thought, the history of tuberculosis in man.

Legible Writing.—The Austrian authorities have issu a rescript calling attention to the law that physicians' pr scriptions must be written in a legible hand.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE INTRODUCTORY LECTURES—PHYSICS AND PHYSIC—SIR JOHN LUBBOCK ON THE USE OF OPPORTUNITIES—THE BEARING ON MEDICINE OF CHEMISTRY—DR. MERCIER ON THE NATURE OF INSANITY—SCARLET FEVER IN LONDON—CHOLERA—SIR RICHARD OWEN.

LONDON, October 5, 1892.

THE winter session at the medical schools begins nominally on October 1st, but as that day fell on Saturday this year, real work has only commenced this week, and, in fact, at most of the schools the formal opening of the session was postponed until Monday last. The custom of having an "introductory lecture" is one which is decidedly on the wane, but it is not yet extinct, and addresses have been delivered at several of the metropolitan medical schools. St. George's Hospital led the van by adhering to the time-honored date of the "First," and Dr. Fowles, of Folkestone, gave an address there on that date on "The Application of Physics to Physic." He pointed out that all changes occurring in physiological and pathological processes, formerly supposed to depend on that unknown quantity "vital force," were really only the action of the recognized forces of Nature on the organs and structures of the body. Almost all the work of surgery was done by the proper application of the laws of physics; surgery was really a department of physics—a physical art. Medicine was rapidly following in the same lines. Physiology was steadily elucidating the ways and doings of animal life; by ways and means connected with physics they are getting to understand better and more purely the movements and functions of respiration, of circulation and digestion, of secretion and excretion, and finally they hoped to understand the most subtle and mysterious of all functions, the operation of the nervous system. Physic, or the sphere of the physician, was the application to diseased or disordered conditions of the ways and means of physiology. They reduced to experiment the disordered state that they might learn its real nature and be enabled to bring it back to order by the use of natural and appropriate means. Schröder, Pasteur, and Chauveau had opened up an entirely new world to us. We had now not only to study the causes as well as the changes of the disease in the body, but also the doings of the bacteria outside the body and within it. Each year showed more clearly the value of physics in the department of preventive medicine. The lecturer then proceeded to point out the manner in which physics might be applied for remedial purposes.

The other introductory lectures were delivered on Monday, 3d inst. Sir John Lubbock gave the address at St. Thomas's Hospital. Pointing out that his hearers were preparing for one of the noblest professions—that of ministering to the health of their fellow-creatures—he said they must be also careful of their own health. Few people perhaps realized how much their health depended on themselves. There was many an invalid of whom it might be said, as Milton said of Hobson, that "ease was his chief disease." He urged them to arrange their work so as never to waste a moment. A certain amount of amusement was desirable, and regular exercise was absolutely necessary to all ordinary constitutions. But a great many people, for want of a little forethought, lost a great deal of time in what was neither work, exercise, or amusement. He would not urge them to read nothing but learned or professional works. On the contrary, it was important to keep up general reading, but he was often astonished at the want of care with which many persons selected their reading. It was important to choose their associates wisely. Referring to the profession they had chosen, he said he hoped they would use their opportunities for the advancement of medical science and the diminution of human suffering. Every one of them might, if he chose, make some contribution to the great edifice of human knowledge. Dr. Billings, in his interesting address on medical literature, delivered before the International Congress, had justly observed that "chance may present to the most obscure practitioner an opportunity for observation which the greatest master may never meet." After reviewing some of the advances in medical science which had been made of late years, Sir John Lubbock urged upon the students the importance of cultivating habits of business. Out of a thousand medical students whose careers had been followed by Sir James Paget, less than twenty had failed entirely, except through gross misbehavior on their own part. In fact, in medicine, as in other professions, if a man made himself useful he would be used.

Dr. Luff gave the introductory lecture at St. Mary's Hospital, and after speaking of the importance of moral character, and uttering a warning as to the dangers of excess in athletics, proceeded to discuss the important bearing on medicine of chemistry. Dr. Luff is an accomplished chemist as well as a practical physician, and was therefore well qualified to deal with this subject. He asserted that those who could spare the time to acquire an extended knowledge of chemistry would become possessed of a factor most useful in the treatment of disease, and most potent in aiding the discovery of some of the hidden secrets of the causation of disease. He did not think it was too much to expect that, in the future, the exact modes of action of drugs would be ascertained; that in connection with many diseases, and especially in the case of the infectious diseases, the poisons produced within the human body would be discovered to which the symptoms of those diseases were due, and that, having discovered those poisons, the method of destroying them or rendering them innocuous by antidotes might be found. He pointed out that although some measure of success had been attained of late years in the treatment of diseases of the individual, yet a much greater measure of success had been attained in the prevention of the diseases of communities. In the future, preventive medicine would doubtless attain to a much higher degree of perfection.

Dr. Mercier gave the address at the Westminster Hospital. At the outset of his discourse he reviewed the altered relations of the medical profession to the public. The intercourse of doctor and patient had become less oracular and more confidential. The old view of disease that regarded the patient as a body, some organ of which was deranged in its working, was now passing away. The new view regarded the patient as an acting, thinking, feeling man, whose power of acting, thinking, and feeling was impaired and needed to be restored. Among the results of our increasing knowledge of the action of the nervous system were the altered views that began to prevail with regard to what might be termed diseases of the body politic, by which was meant not widespread maladies affecting large numbers of individuals, such as influenza or cholera, but disorders of the community which might coexist with a good standard of health in the individuals of which the community was composed—disorders which impaired the efficiency of the social body. Such social maladies were crime, pauperism, and insanity. Dr. Mercier, who is a well-known alienist physician, then proceeded to discuss these conditions. He contended that, different as they were in superficial features, they exhibited upon close investigation such substantial similarity that they might be regarded as several branches of one stock. The pauper, the criminal, and the lunatic were alike in being stragglers from the great army of civilization. It had been established beyond cavil by Lombroso and the school of criminal anthropologists that the criminal man was of a different physical organization from the normal man, and resembled the lunatic in many respects. While every insane person was potentially a pauper, nearly all the insane were potential criminals also. There was a

constant transferrence of individuals from one class to the other. Dr. Mercier also contended that the same remedial agent—compulsory employment—was used efficaciously in each of the three disorders. The practical bearing of the view advocated was to be found in the modification of treatment that would follow if the close relationship of the three maladies were admitted. The lunatic could be detained if in the opinion of his physician he was not sufficiently recovered to render him a fit person to be entrusted with his liberty; in the case of the criminal this provision did not exist. It was certain that if the reclamation of the criminal was to be effected, the period of his detention must be indefinite in duration, and must depend on the amelioration of his character. The value of these speculations from a medical point of view was claimed by the lecturer to consist in the broadened and more accurate conception that they afforded of the nature of insanity and allied disorders. The explanation of such phenomena was to be found, not in visible structural peculiarities, but in the operation of biological and sociological laws; not in alterations of the brain, even though such alterations existed, but in the ancestral history of the individual, and in the complex interactions between the forces that animated him and the conditions in which he was placed.

At University College the introductory address was given by Mr. S. J. Hutchinson, Dental Surgeon to the Hospital, and at the Middlesex Hospital, Dr. J. J. Pringle, Physician to the Skin Department, gave the lecture.

Scarlet fever is still on the increase in London, and the accommodation afforded by the hospitals of the Metropolitan Asylum's Board is quite inadequate for the present needs, although last week these institutions contained 3,823 cases—a large proportion of these being cases of scarlet fever. An additional temporary hospital is, however, to be opened this week.

There are no cases of Asiatic cholera now in England though deaths from choleraic diarrhœa continue to be reported from time to time, but only in small numbers and singly.

Sir Richard Owen is still in a critical condition, notwithstanding that he improved considerably recently.

SOUTHERN MEDICAL EDUCATION.

To the Editor of the Medical Record.

Sir: In your issue for September 3, 1892, you purpose to quote from the *Atlanta Medical and Surgical Journal* a list of applications for licenses from the Medical Boards of Virginia and Alabama, but the Virginia figures are omitted.

If you will consult an editorial in the *Virginia Medical Monthly* for July, 1892, page 323, you will find the computations given below. They conjointly apply to Virginia and Alabama:

"Per cent. of Rejections of Graduates of Southern Medical Colleges, 13.7; ditto, Western Colleges, 19.4; ditto, Northern Colleges, 29.2."

The basis of the figures of the *Atlanta Journal* is somewhat unfair to the West and South. The Eclectic schools of the West and South lower the good standing of these two sections, and the graduates of the schools in Washington, D. C., some of them negroes, are accredited to the Southern Colleges. We beg to be excused from such comparisons, and such geography.

Great are the Northern schools, long live the Northern Schools, but unfortunately students will attend the low-grade schools in the West and South. And, strange to relate, several of the graduates of such schools are Army Surgeons, and quite a number of them are Naval Surgeons, while others of them lead in the teaching and the practice of Surgery and Gynecology in the greatest of orthodox medical centres, New York City.

Thomas R. Evans, M.D.

Burlington, Ia

CHOLERA IN NEW YORK IN 1832.

To the Editor of the Medical Record.

Sir: The following short account of my experience with cholera in 1832, and of the treatment employed, may be of interest to the readers of the Medical Record. At that time I was a senior student in Professor John M. Smith's office, reading all that came to hand of cholera and its treatment. The first case in the city was announced on a Sunday morning at James Slip. I immediately went there. In a small attic room of a two story house, one young man lay dead from cholera, and another on the other side of the room was in the last stage of collapse. I remained there several hours to learn what I could of cholera.

As many of the city physicians had fled, senior students were in demand to carry out the prescriptions of the hospital physicians. I received an appointment in the Rivington Street Hospital, and served the whole time; remaining there two weeks after it had virtually closed, to do up the writing. My home was with my parents in Cherry Street, between Roosevelt and Franklin Square, where I spent one night in the week. My sleeping time in the hospital was from 6 P.M. till 12 M., on a cot on the platform in view of all the patients on the first floor. A half-peck of rather hard peaches was brought in about 11 A.M. daily. I used to eat twelve of these with sugar every day at 11 A.M., at 4 P.M., and at 12 M., when called from my slumber to duty. They at no time disagreed with me. One evening on my way home, having eaten heartily of soft toast, I felt a fulness at the epigastrium. The next morning, just before day light, I had an evacuation of seemingly a gallon of water as soon as it was light I took five, five-grain blue pills, and went to Pearl Street opposite Centre Street, and had a hot bath, and then rode in a carriage to the hospital for duty. I was very weak, and lay down all day except when called up. I continued well after that. I cannot tell the internal treatment at the hospital, but there was no success, as mild cases only recovered. The external treatment with every patient was to be scrubbed thoroughly with stiff brushes, loaded with Cayenne pepper and blue mass. Five men to each patient with long handled brushes, one to each arm, one to each leg, and one for the body, as soon as they could be disrobed after arrival. This was to secure stimulant and mercurial effect. One man, after passing through all the routine of treatment, was left to breathe his last, resembling a terribly emaciated corpse. He then had a quart of bicarbonate of soda solution thrown into his veins at the bend of the arm. It was strange to see him revive from this immovable, shrunken, death like condition, the veins of his nose becoming filled, the skin reddening and expanding, then his limbs beginning to move, and he to survive. His life was prolonged some thirty hours. It was a common thing for those who died through the day and who were put in a coffin at night, to be found the next morning with their arms out of the coffin, or their hands up to their head. A girl about eleven years old, apparently dead, with her eyes partly open and a film covering the lower half, for some undefined reason was left when the others were taken out. Her appearance did not change, and so she was left for five days. I think on the sixth there was some sign of life. She recovered, but with ulcerated corneas.

It was my business to take the hospital report to the City Hall at 12 noon daily. Returning one day when the hospital was about to close, a fellow-student wished to know our success in treatment. I said we had none, everything failed. He said that he had lately been successful with some patients. That he gave twenty grains of calomel with two grains of camphor every two hours until some green appeared in the stools. A dozen or so small lumps of ice were allowed at a time to quench the thirst, and a sinapism was placed over the stomach. When the hospital was virtually closed, and I left the

one, a man was brought in, seemingly as bad as any e had had, with the characteristic symptoms—intense irst, vomiting, purging, and cramps of the extremities. treated him as suggested by my friend Olliffe. The ice as retained, and after two or three doses of the calomel nd camphor a greenish fluid appeared. I then followed ie calomel in due time with castor-oil. A few days after nother man was brought in in the same condition. He as treated the same way, and as speedily recovered. In l of our cholera seasons since, if I saw my patient before ollapse set in, I have been successful with the same eatment, in whole or in part. The ejections upward nd downward, like rice-water in appearance, indicate iat there is inaction of the liver. The sedative influ- ce of twenty grains of calomel with the camphor quiets ie stomach and acts speedily upon the liver, killing the isonous bacilli and causing the speedy disappearance cholera symptoms. The ice being retained, perhaps ded by the sinapism, relieves the thirst. One cholera ason, 1849, so many physicians left my neighborhood, at I had from fifty to seventy patients to see daily, eat- g my food often along the street. I lost no patients at is time with cholera.

In 1854 I was requested to go to English Neighbor- ood, now Fair View, six and a half miles from Ho- oken, as an epidemic of cholera had broken out there om a load of decayed fish. All died, so that the doc- r refused to go, saying it was of no use. The gentle- an, Mr. Daniel Talcott, a committee of one from the eighborhood, assured me of my pay by offering a blank ieck to fill at my own price, and a carriage to take me ick and forth. I went; found some on the border of llapse. All recovered with the same treatment. I was id by one family $150, and received a large, elegantly nbossed silver pitcher, engraved, as a token of successful eatment of cholera in English Neighborhood in 1854. r. Talcott is still living, doing business in this city as real estate agent, having left the cotton trade, but still es at English Neighborhood. He will give particulars that fearful time, that I am now unable to do.

Respectfully,

EDWARD VANDERPOEL, M.D.

NEW YORK, September 30, 1892.

Medical Practice in Oklahoma.—Dr. E. O. Barker, of e Oklahoma Board of Medical Examiners, writes to the *'edical Age* concerning the law regulating medical prac- e in that territory. A certificate authorizing us to prac e medicine may be obtained on presentation of a diploma om a medical college of good standing and the payment a fee of two dollars. If the applicant be not a gradu- e of a recognized medical college, he must submit to an amination prescribed by the Territorial Board of Med- al Examiners If the result of this examination be sat- factory, a certificate to that effect will be issued. The e for examination is twenty dollars, one-half of which ill be returned in case of failure to pass. Certificates of aduation have been issued, up to the present time, to ie hundred and seventy-one applicants, five of whom ere women. One diploma has been rejected as from a audulent college. Certificates of examination have been sued to twenty-two, all men. A number of arrests for olation of the law have been made, all resulting in con- ction, so far as they have come to trial.

Disinfectants.—Experiments recently made by the ealth Board of this city concerning the relative germi- dal properties of various substances resulted as follows, e disinfectants being arranged in the order of their fectiveness: Corrosive sublimate, 64 grains to the gal- n; carbolic acid, five per cent. solution; bromine, one und to 200 gallons; permanganate of potash, $7\frac{3}{4}$ ounces 200 gallons; chloride of lime, 4 ounces to the gallon; lphate of iron, $1\frac{1}{2}$ pound to the gallon; sulphate of nc, 4 ounces to the gallon; common salt, 2 ounces to e gallon.

Therapeutic Hints.

The Therapeutic Value of Calcium Salts.—Dr. Germain Sée advises the more general employment of calcium salts in medicine in preference to those of potassium or sodium. Iodide and bromide of calcium are especially useful, he says, when we desire to obtain the effects of bromine or iodine on the organism. They contain a greater percentage of iodine and bromine than any other salts, and furthermore, calcium has neither the often undesirable activity of potassium, nor the inactivity of sodium. Iodide of calcium is well borne by the stomach when the potassium salt disagrees, and it is fully as efficacious as the latter in syphilis, and in its action on the heart and respiration. Bromide and chloride of calcium are useful in a great many diseased conditions of the stomach, and in dyspepsia. They may also be substituted with advantage for carbonate of calcium when it is desired to restore lime to the organism, for chalk is absorbed with difficulty, the greater part of it passing away unchanged from the bowels.

Treatment of Chorea.—Dr. Baumel believes that in the great majority of cases of chorea the predisposing cause is anæmia, the exciting cause being dentition, especially the evolution of the large molar teeth from the sixth to the fourteenth years. He uses the following:

℞. Potassi bromidi ..... gr. xxx.
Syr. aurant. cort. ..... ʒj.
Aquæ ..... ʒ iij.
M. Sig.: To be taken in the course of twenty-four hours.

In addition to this he gives one grain of reduced iron morning and evening, together with a tablespoonful of decoction of cinchona in a glass of sweetened milk.

Paroxysmal Tachycardia.—The following is the formula recommended by Huchard in the treatment of this condition:

℞. Quininæ sulphatis,
Extracti ergoti aquosi ..... āā gr. lxxx.
Extracti nucis vomicæ ..... gr. viij.
M. et div. in pill No. 40. Sig.: Two pills, two or three times a day, for a fortnight.

This remedy, which is especially indicated in cases in which there is diminished arterial pressure, may be followed by from 10 to 20 drops daily of Pearson's solution of arsenic, continued for six or eight weeks.

Hæmorrhoids.—Dr. Kosobudski uses the following ointment with good effect in hæmorrhoids:

℞. Chrysarobin ..... gr. xl.
Iodoform ..... gr. xv.
Extract of belladonna ..... ʒ ss.
Vaselin ..... ʒ jss.
M. Sig.: For external use.

Lamb's Blood-serum in Syphilis.—Dr. Tommassoli reports in the *Gazzetta degli Ospitali*, November 28, 1892, six cases of syphilis treated by the daily injection of $\frac{1}{2}$ to 2 drachms of lamb's blood-serum. The serum was injected into the fleshy parts of the nates, and the operation was followed by massage of the part. He asserts that all the manifestations of the disease disappeared with a rapidity that he had never seen in any other mode of treatment.

Antidote for Carbolic Acid.—A strong solution of sodium sulphate, introduced into the stomach through a tube if the patient is unable to swallow, is reported to be an efficacious antidote in cases of poisoning by carbolic acid.

Local Anæsthesia is said by Dobisch to be readily produced, in about one minute, by a spray of menthol, one part; chloroform, ten parts; and ether, fifteen parts The anæsthesia continues for from two to six minutes, and may be prolonged indefinitely by the renewal of the spray for a few seconds at a time, as needed.

Vaginismus.—The following is recommended by De Sinéty as affording relief in obstinate cases of vaginismus:

R.	Thymol	gr. iij.
	Extr. belladonnæ	gr. xij.
	Potassii bromidi	ʒ ss.
	Ol. theobromæ	ʒ iv.

M. et ft. suppositoria No. iv. Sig.: One suppository, as needed.

Habitual Abortion.—Dr. Turrazo has obtained excellent results in the treatment of frequent and habitual abortion by means of assafœtida. As soon as pregnancy is diagnosed he prescribes pills of assafœtida, containing one and one-half grain each; beginning with two pills a day, and gradually increasing to ten. After maintaining the administration at this amount for some time, the number of pills is very gradually decreased, but the remedy is not wholly discontinued until the normal term is reached.

Salol in Infantile Diarrhœa.—Dr. Mensi speaks well of the action of salol in the diarrhœa of children. It produces, he holds, perfect antisepsis of the intestinal canal, rapidly arrests the watery discharges, and is non-irritating to the gastric mucous membrane. He prescribes it in daily doses of from three to thirty grains, according to the age of the child and the gravity of the disease.

Catarrh Snuffs.—Dr. Capitan, writing in *La Médecine moderne*, recommends the use of the following powder as a snuff at the beginning of a coryza:

R.	Tannin	gr. xv.
	Salicylic acid	gr. xx.
	Salol	ʒ ij.
	Boric acid	ʒ j.

This powder is irritating to the mucous membrane, and therefore ought not to be used after the first twelve hours. The patient may later use a snuff composed of equal parts of boric acid and Venetian talc. The following has been advised in cases of chronic coryza:

R.	Menthol	gr. x.
	Sodium biborate,	
	Potassium chlorate	āā ʒ ss.

Emulsion of Iodoform in Echinococcus Cysts.—Professor Billroth evacuates the cyst of its contents, injects an emulsion of iodoform, and then closes the wound. If the cyst be voluminous, there is danger of iodoform poisoning. This method was tried in four cases with successful results.—*Lancet-Clinic.*

Resorcin in Malaria.—Dr. Samuel Wolfe speaks highly of resorcin in the treatment of obstinate malarial conditions. He gives it according to the following formula:

R.	Resorcin	ʒ iij.
	Tr. eucalypti	fl. ʒ j.
	Syr. limonis	fl. ʒ ij.
	Aquæ	fl. ʒ j.

M. Sig.: Teaspoonful three times daily.—*American Therapist.*

Treatment of the Algid Stage of Cholera.—Dr. Mayländer describes, in the *Berliner Klinische Wochenschrift* of September 5, 1892, the treatment employed with marked success by Dr. Giacich for cholera in the algid stage. His aim was to support the failing heart, and for this purpose he gave ammoniac internally and ether hypodermically, and also administered alcohol freely. Marked improvement in the general condition was noted within two hours after the institution of this mode of treatment, and over fifty per cent. of those who had reached the algid stage were saved.

Vomiting of Pregnancy.—Dr. Weil recommends that ten drops of a twenty per cent. solution of menthol in olive-oil, dropped on powdered sugar and sugar sprinkled over it, be taken whenever nausea appears. By this means relief can be obtained, he says, in the most severe cases of apparently uncontrollable vomiting.

New Instruments.

THE ESSENTIALS OF A GOOD STETHOSCOPE.

By CHARLES DENISON, A.M., M.D.,
NEW YORK.

I HAVE been promising myself for some time to write protest against the frauds of instrument-makers in t manufacture of the stethoscope which bears my nam My instrument was not patented, as it should have be for the purpose of needed regulation as to the quality work and reasonableness of price. Therefore it is ea for an instrument-dealer to order a lot made by an ir sponsible manufacturer, and sell them to unsuspecti medical men, as the real article, at an unreasonable prof This has been done in two instances in New York, a one in Chicago, to my knowledge. In consequence r attention has been called to the most awkward and i perfect imitations, under the name of "The Denis Stethoscope," and I have been chagrined to see join uneven and loose, tubes impervious or partly occlude and especially the flexible portion made with inflexit rubber tubing, with no regard whatever to my dire tions.

In London, Down Brothers have made a pretty f instrument, excepting their poor adjustment of the sprin but in this country George Tiemann & Co. are the or ones whose make I can recommend. They have cor nearer than any other manufacturer that I know of in fi ing the requirements of a perfect binaural stethosco which desiderata I will state as follows:

1st. **The Smooth Inner Calibre,** large size and grad ally decreasing from the bell to the ear-ending, in imit tion of the speaking-tubes used for deaf persons. T law of sound is like that of light transmission, *i.e.*, t angles of incidence and reflection are equal; and t transmission is aided by the trumpet-shaped bell a gradually decreasing size of the smooth inner surface the tubes.

2d. **The Continuous Transmission of Sound.**—Th must be natural, so hard rubber or celluloid are pref able to metal for the tubes, as the latter gives a hi pitch and metallic sound to the sounds heard. The join between the bells and the main tube, and between t arms and the flexible tubes, are made by the even a perfect fitting of slightly conical tubes into each oth making the whole instrument as if of one piece, as far the transmission of sound is concerned. Probably larger part of the sound is transmitted through the steth scopic substance than through the hollow cavity.

3d. **The Construction of the Flexible Tubes.**—T coiled wire for these tubes, which lines the usual rubb tubes and is itself lined with smooth soft rubber, is ma to impinge at each end of each tube against the gut percha, so that a nearly perfect transmission of sound obtained. This is the part that Tiemann & Co. alo have succeeded in rightly making, and it is an importa feature of my stethoscope.

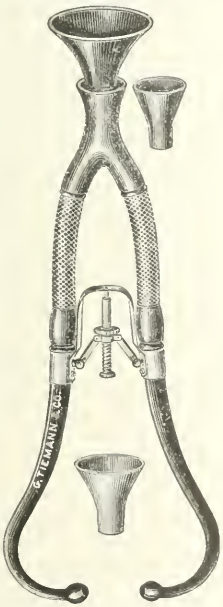
4th. **The Ear Endings** as lately made are acor shaped, with openings so turned as to be directed direc toward the drums of the ears. This is a compromi from what I wanted, which was to have the lower a forward side of these tips bulge so as to fill the space b hind the tragus, and leave the hole above and back i mediately in front of the auditory canal. The difficul of fitting variously shaped ears with perfectly adapt ear-tips is considerable with any other than the ev conical pattern, but, I think, ought to be overcome.

5th. **The Spring Attachment** to pull together t arms is adjustable so that all the pressure of the ear-t can be obtained that the listener can stand with comfo This much pressure is desirable for perfect transmissi of sound.

6th. **The Ordinary Bell Endings** are as follows: T stationary bell, with slightly flaring rim one and one-eigh

h in diameter, which is large enough to use in examination of infants and in the detection of valvular ions. The medium-sized bell, which has a rim one and half inch in diameter and sufficiently flaring to give ood impinging surface against the chest, is the size linarily used. The soft rubber bell, rather thin and ible, is intended to crowd into the medium-sized bell, ing a one-fourth inch projecting rim of soft rubber use on uneven surfaces, as in much emaciated conaptives.

th. **The Large Bell for Stethoscopic Percussion.**—is is not, as has been assumed, for use held against the st-wall, but for gathering the waves of sound emitted m the open mouth during expiration while forcible cussion is being made over portions of the lung where tening, bronchiectasis, or excavation is suspected. e concussion of the air contained in the thorax carries h it the succussion, the cavernous, or the cracked-tal sounds which accompany the three above-named ditions, and by holding this large bell two inches from patient's mouth, and percussing during expiration, they distinguished better than can be done in any other y. Indeed, in thin chested sons with superficial exations connected with a in bronchus, the fingerl percussion will nicely l accurately outline the its of the excavation. e cracked-pot or hollow nds are altered in various ys, a slushy or succussion ility being sometimes imted to either, according the amount of moisture breaking down which comcates the condition. I ieve that the importance the question of the first aking down of lung tisselevates this stethoscopic cussion to a first place in art of physical diagnosis. l is certainly coequal with dinary percussion, and sec-d, if at all, only to auscultion.



The test I suggest of a od stethoscope is not, as umed by Dr. Valentine in article in the MEDICAL CORD of July 16th, to hold medium-sized bell against face of a watch, but put watch on a show-case or table, cover it with the palm the hand, and then press the bell against the back of hand. The clearness with which the working of the chinery is heard is the criterion of perfection in the inment. By this test seven-eighths of the other stethospes sold fall short of their proper utility. I am willing ave my instrument, if properly made, tried by this test l if anyone will improve on mine as much as I have imved on the ordinary kind, I will have his make if it costs o. I do not believe, however, that there is room enough the perfect reproduction of auscultation sounds for so ch improvement, unless it would be with a telephonic thoscope, which would necessitate an electric battery ompaniment.

Portability and cheapness of construction are not cral points in a good stethoscope. Utility should be sidered first, last, and chiefly. Yet the former points uld not be lost sight of in making my instrument. It uld be as short and compact as flexibility and conience of use will allow, and should be proportioned ts different parts about as shown in the accompanycut.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 15. 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	32	15
Scarlet fever	63	6
Cerebro-spinal meningitis	0	3
Measles	28	1
Diphtheria	59	14
Small-pox	9	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Tendoplastic Operation.—Dr. H. Sporon describes, in the *Hospitals Tidende*, vol. ix., No. 50, an ingenious method of elongating a tendon. After exposing the tendon he makes in it two parallel longitudinal incisions of equal length, one of which begins about one-third inch above the other. Then, from the upper end of the first and the lower end of the second, he makes incisions to the edge of the tendon in opposite directions, at right angles to the primary incisions, as shown in the accompanying diagram. [ ] This done, it is possible to elongate the tendon as much as may be desired, according to the length of the parallel incisions first made, without destroying its continuity. In a case of talipes equinus so treated the patient was able to put his heel to the ground and walk about, with the aid of a stick, in four days after the operation.

Suture of the Lung.—At a recent meeting of the Paris Academy of Medicine, Dr. Guermonprez reported an interesting case of suture of the lung in a young man of eighteen years (*Journal des Sciences Médicales de Lille*, September 2, 1892). The patient had pyopneumothorax following a pleurisy. Thoracoplasty was practised, six ribs being exsected, when the gaping orifice of the broncho-pleural fistula was readily seen. Some difficulty was experienced in closing the opening, as one of the sutures broke and another tore through the pulmonary tissue, but finally three catgut sutures were passed, one of them going directly through the centre of the fistulous track and embracing a sufficiently large portion of the lung tissue to hold firmly. As soon as these sutures were drawn together the passage of air through the fistula ceased, and on the thirty-eighth day after the operation cicatrization was complete.

Post-Influenzal Chorea.—Dr. Corrado Ferrarini, writing in *Lo Sperimentale*, relates a case of chorea, following an attack of influenza, in a child ten years of age. The first manifestations of the disease appeared in the face about twelve days after the beginning of the influenza. Then the muscles of the upper extremities, and finally those of the lower limbs, became involved. The author attributed the chorea to poisoning by the toxine of influenza, and thinks that it is frequently due to an infection of some sort occurring in those already predisposed.

Docking Horses.—There is a law in Massachusetts against the practice of docking horses, and the Society for the Prevention of Cruelty to Animals has succeeded recently in obtaining several convictions under its provisions. The law reads as follows: "Whoever cuts the solid part of the tail of any horse in the operation known as docking, or by any other operation performed for the purpose of shortening the tail, and whoever shall cause the same to be done, or assist in doing such cutting, unless the same is proved to be a benefit to the horse, shall be punished by imprisonment in the jail not exceeding

one year, or by fine of not less than one hundred nor more than two hundred and fifty dollars. One-half of all fines collected under this act, upon or resulting from the complaint or information of an officer or agent of the Massachusetts Society for the Prevention of Cruelty to Animals, shall be paid over to said Society in aid of the benevolent objects for which it was incorporated." A similar law was also passed at the last session of Congress for the District of Columbia.

Reflex Toothache.—In a case of toothache for which it is difficult to find a cause, the possibility of its being a reflex expression of trouble in some other part of the body, or in some other tooth, must not be forgotten. Slight operations in the nasal passages, such as the removal of adenoid growths and the cauterization of hypertrophied mucous membrane covering the turbinated bones, may be followed by toothache. Diseases of the eye and ear, of the stomach, of the uterus, and the condition of pregnancy may be accompanied by pain in the teeth.—Dr. C. P. Briggs, in the *International Dental Journal*.

Morvan's Disease, according to Dr. Zambaco, is really nothing more than a form of leprosy. The same author holds also that there are two distinct varieties of syringomyelia, one of which is likewise leprosy. In this variety of syringomyelia there is the claw hand like that met with in anæsthetic leprosy, and the patients also have other sensory and trophic symptoms of the latter disease.

The Ice in Paris is to receive more attention from the health authorities than it has had hitherto. It has been forbidden to cut ice from, or to make ice artificially from, the water of the Epinay-Enghien basin, a pool connected with the river Seine, and receiving from it the greater part of the sewage of Paris. Strange to say, much of the ice supply of Paris has been derived from this source. The health authorities have also appointed ice inspectors, who will from time to time make analyses and bacteriological examinations of various specimens of ice obtained from the dealers.

Vomiting of Pregnancy, when severe, is treated by Dr. Neichtoube in the following way :

℞. Cocaine sulphat..... gm. 1
Aq. dest..... gm. 60

Take ten drops. If necessary, repeat in an hour. If no effect is produced, repeat at the end of three hours. The following day give five or six drops three times, and keep it up until the vomiting ceases. At the same time apply to the vagina tampons covered with a two per cent. cocaine ointment.

Simple Tests for Impurities in Water.—The following methods of determining the presence of impurities in water are given by Walling : 1. For organic matter, put a little of the sample into a beaker, add two or three drops of dilute sulphuric acid and color distinctly with a solution of permanganate of potassium. If much organic matter is present the color of the permanganate becomes discharged almost immediately ; if less or very little, it takes longer to decolorize. If the color has not changed in twenty-five or thirty minutes it is safe to assume that organic matter was not present. This is a tolerably reliable test. 2. For nitrites, a little sulphuric acid added to the water forms nitrous acid if nitrites are present, which is easily detected by its power of liberating iodine from iodide of potassium. A little starch paste is mixed with a small quantity of a solution of potassium iodide, and the mixture added to the suspected water containing the sulphuric acid. If nitrites are present the nitrous acid formed liberates the iodine from the iodide, which turns blue with starch. This indirect method is a ready means for detecting the nitrites if present in not too small a quantity. 3. Nitrates are detected by converting into nitric acid, which turns morphia red. A portion of the water is evaporated to dryness the residue treated with a drop of strong sulphuric aci (which makes nitric acid of the nitrate) and a portion c morphine added. If nitrate is present the morphin gives red color. 4. For ammonia, Nessler's reagent i by far the best test. It may be made by dissolving eigh teen grains of oxide of potassium in a little water, addin solution of mercuric chloride until the red iodide c mercury first formed redissolves upon agitation. To th is added a solution of fifty grains of caustic potassa an distilled water to make eight ounces. This reagent wi detect 0.00375 of a grain in a pint of water by giving yellow color. A reddish color or precipitate forms wit larger quantities of ammonia. 5. Albuminoid matte requires a more elaborated proceeding for its detection If all of the above were found it is hardly necessary t go to the trouble of looking for albuminoids ; the wate would be unwholesome even if they were not present.—*Pharmaceutical Era.*

A Defence of the Use of Opium by Women in India—At a recent meeting of the Woman's Missionary Con ference in Toronto, Miss Beatty, a medical missionar from the western part of India, spoke against the effort making to restrict the use of opium by the natives of tha country. She said it would be cruel to take it awa from suffering womanhood until civilization had opene the door of the zenanas to medical men or there wer enough women doctors to relieve the agonies whic women suffer and must bear without treatment. Opiur is inexpensive. All women take it. All babies ar drugged with it, and the poor little child-wives are r lieved by its aid. "I have seen," said Miss Beatty, " little girl of thirteen with her own baby on her lap. was drugged and no trouble to her. How could it b when it was asleep ? And she would put up her littl hands and plead for a doll to play with while she wa free from the care of her little one. While the presei awful state of things maintains in India, opium is som thing to thank God for."

Dog Meat.—A French paper says that the number c dogs slaughtered at the abattoirs in Munich has increase amazingly in the past few months. The taste for dog flesh is said to have been imported by Italian laborer who have recently come in large numbers to the Bava rian capital. The meat is not used only as an adulterai for sausages, but is eaten openly, under its own nam prepared in various ways.

Law Against "Sweating."—Several tailors living the Hebrew quarters on the east side of the Bowery hav recently been arrested for violating the factory inspectio law. One of the two provisions of this law, designed t break up the sweating system, which they are accused c violating, reads as follows : "No room or rooms, apartmer or apartments in any tenement or dwelling-house shall b used for the manufacture of coats, vests, trousers, kne pants, overalls, cloaks, furs, fur trimmings, fur garment shirts, purses, feathers, artificial flowers, or cigars, excep ing by the immediate members of the family livir therein."

The other provides that "not less than two hundre and fifty cubic feet of air space shall be allowed for eac person in any workroom where persons are employe during the hours between six o'clock in the morning ar six o'clock in the evening, and not less than four hundre cubic feet of air space shall be provided for each perso in any workroom where persons are employed betwe six o'clock in the evening and six o'clock in the mor ing."

These laws are excellent, but they are not, and prob bly cannot, be strictly enforced. Offenders, when caugh are fined, and then go back and continue to break th law. The only way to prevent sweating, or at least reduce its evils to a minimum, would be to prohibit th making of garments of any kind in tenement-houses.

A CLINICAL REPORT OF GALL-BLADDER OPERATIONS.[1]

BY RUFUS B. HALL, M.D.,

CINCINNATI, O.

THE following seven cases comprise all of the gall-bladder operations I have performed, and are reported in the order of their occurrence. I put the cases on record as so much clinical material, to guide us in our future work in this comparatively new operation. I have gained many valuable points in the management of these cases, and hope they will not be uninteresting to you.

CASE I.—Mrs. B——, aged thirty-nine, Cincinnati, O. Patient of Dr. Stevens. Operation was made April 13, 1890, and reported in full in the *Times and Register* of Philadelphia, July 5, 1890, and I will give but a short abstract of the case here. At the time of the operation the patient had been suffering from complete obstruction of the common duct for more than three weeks, and the cholæmia was profound. She was in a dazed condition, listless, and did not appear to notice anything or anyone about her. Pulse, 100; temperature, 97½° F. The liver was enlarged, the lower border was easily defined about four inches below the ribs. She vomited a little glairy mucus every few minutes. The patient appeared to be in a dying condition. Any operative interference seemed to promise nothing but a fatal termination, yet, as it afforded some hope, the friends decided to have the operation made. Upon opening the peritoneal cavity, firm adhesions were encountered with omentum, intestine, and gall-bladder. After these were separated, I could detect several stones in the enlarged gall bladder, which was aspirated and incised. Four gall-stones which were lying loose in the gall-bladder were removed, a fifth stone was found impacted in the common duct and removed. The sinus was closed on the twenty-first day. The patient complained of nausea but little after the third day, and vomited but twice after the operation was made. On the third day she retained liquid food, and on the fifth day she had a ravenous appetite. On the twenty-eighth day she was able to superintend her household duties.

CASE II.—Mrs. F——, aged fifty-two, was seen by me with her physician, Dr. Dorr, at her home near Lower Salem, O., February 16, 1891. For seven or eight years she had suffered from some obscure disease in the region of the liver. That organ was very markedly enlarged during the acute and severe attacks of pain from which she suffered, at irregular intervals, for the past four or five years. The enlargement gradually subsided after the acute attacks were over, yet never entirely disappeared for at least one year before the operation was made. She was under the professional care of several of the best-known physicians in her locality for months before the operation, yet she received little if any benefit other than palliative. Up to five or six weeks before my visit she had never been jaundiced, except for a slight discoloration of the conjunctiva occasionally after the more severe attacks of pain. About five weeks before my visit, after suffering from a severe attack of pain of several days' duration, she gradually developed jaundice, which grew more pronounced from day to day, until at the end of ten days it was profound, which condition remained at the time of my visit. She was markedly emaciated, and examination revealed the fact that the liver was enlarged to a point about three inches below the ribs, and in the region of the gall-bladder could be detected a distinct pear-shaped enlargement the size of a pint-cup, which I believe was the enlarged gall-bladder. My diagnosis was gall-stones with the obstruction of the common duct, and I advised an operation, which, however, was not accepted until two weeks afterward, at which time the patient was in a very bad condition for an operation, with a pulse of 112, temperature 98° F., and vomiting a little mucus every few minutes. She had been unable to retain the blandest food in the stomach for the past ten days.

March 2d she entered my private hospital to have the operation made, which was done the 7th. Present, Drs. Van Meter, Ricketts, and Reed. After the abdomen was opened the gall-bladder was found to be enlarged and to contain a number of gall-stones. After removing twenty ounces of bile with the aspirator, the gall-bladder was incised, and three large stones and several small ones were removed without difficulty. I sought for the obstruction in the common duct, and found a stone, larger than the end of the finger, firmly impacted. I also discovered for the first time a new-growth larger than a walnut, which involved the duct. After the stone was removed I was unable to pass a probe through the duct into the intestine, owing to the obstruction from the new-growth, which proved to be malignant disease of the head of the pancreas. The operation was made in the usual manner, by stitching the opening in the gall-bladder to the abdominal wall and draining it. The wound united perfectly. She had no inflammatory trouble following the operation. The highest temperature was 100° F. She gradually failed in strength, and died from exhaustion the sixth day after the operation. The unfortunate termination of this case is one that must occur if the operation for gall-stones is deferred until after a new-growth develops. There is no doubt in my mind but that the long-continued irritation from the presence of gall-stone in the gall-bladder, and the consequent repeated attacks of hepatitis which so frequently occur, favor the development of malignant disease in or about the gall-ducts. I am aware of the fact that this statement will be challenged; but if we recall the fact that a patient suffering from gall-stone usually gives a history of some obscure hepatic difficulty for years, which gradually grows worse until the operation or death occurs, and an autopsy reveals the fact that the patient not only had gall-stones, but also malignant disease in or about the ducts; and again, if we recall the fact that patients may and usually do live for years after they have developed gall-stone, provided the common duct is not obstructed, we must accept this view. On the other hand, these patients die within a few weeks after the development of malignant disease. Now, with these facts before us it is not a difficult matter to associate cause and effect in the two maladies. If we find that it is a fact that patients suffering from the presence of gall-stone are predisposed to malignant disease, it will be a very forcible argument in favor of an early operation for their removal. It is only necessary for us to trace the cases dying from obscure hepatic diseases and record the diagnosis made at autopsy to be convinced of the frequency of the co-

[1] Read before the American Association of Obstetricians and Gynecologists, St. Louis, Mo., September 20, 1892.

existence of gall-stones and malignant disease about the gall-ducts. Granting the correctness of this assertion, would it not be advisable to make an exploratory incision in all of those chronic cases suffering from obscure hepatic difficulties, where health is destroyed and life endangered, and where a correct diagnosis is otherwise impossible? I, for one, am convinced that this is the correct doctrine. My third case will illustrate this and justify the procedure.

Case III.—Mrs. S——, aged thirty-three, Louistown, Pa., was seen in consultation at her home with her physician, Dr. Harshberger, September 20, 1891. She gave a history of having suffered severe pain in the hepatic region about nine years ago, which was believed by her medical attendant to be hepatic colic. During the following four or five years she had had a number of similar attacks of pain, each one confining her to the bed for a week or more. About five years ago she had another attack, but much more severe, which continued for about five weeks. During this attack she required large doses of morphine several times daily to make her existence tolerable. From this time on she was confined to her room, and a greater part of the time to her bed. If she would attempt to walk about the room the pain would at once return, and it was only a few weeks later that the exertion required to get out of bed would at once cause a terrific attack of pain in the hepatic region. For this reason only she chose to keep her bed rather than endure the pain. After she adopted this plan she had the attacks of pain at intervals of from three to six weeks, these lasting from six to twenty hours, always requiring large doses of morphine for relief. At the time of my visit the patient was emaciated, estimated weight seventy-five pounds, while her former weight had been one hundred and twenty-six pounds. She was afraid to turn herself in bed for fear of bringing on an attack of pain. The skin was clear, no enlargement over the region of the liver or gall-bladder. There was slight tenderness over the locality of the gall-bladder, on very deep pressure. The patient was a martyr from the pain, and was so anxious for anything which promised relief, that I advised an exploration, which was done October 19th, believing we would find gall-stones to be the cause of her pain. Upon opening the abdomen we found the gall-bladder very much contracted. The walls were fully half an inch in thickness, and the cavity would not have held half an ounce but that was packed full of gall-stones, ninety-one in number. One large stone was impacted in the cystic duct, and apparently the duct was closed from inflammatory changes upon both sides of this stone. It was with great difficulty that this could be removed. After making a communication with the gall-bladder by means of a sharp pair of pointed scissors, using them much the same as we would an augur to bore a hole with, until we got down to the stone, we succeeded in breaking it up and removing it in pieces. The patient made a good recovery, and is now free from pain and enjoying most excellent health. The result in this case illustrates the wisdom of exploration in these doubtful cases.

Case IV.—Mrs. F——, aged fifty, Cincinnati, O., has been a sufferer for about one year from some obscure hepatic difficulty, during which time she has had several severe attacks of pain, of two to three weeks' duration, accompanied with an enlargement in the region of the gall-bladder, and slight jaundice. When I first saw the case with her physician, Dr. Berchard, she had been ill for ten days. The liver was enlarged and there was a distinct enlargement over the gall-bladder, with well-marked jaundice. She vomited a little mucus every few minutes, and the pain was so severe that she required morphine several times daily. From the fact that she had been ill for more than a year and was unable to secure relief from the best medical treatment, and had every indication of obstruction of the common duct, I advised an operation, which was at once accepted. The operation was made March 5, 1892; the gall-bladder was very largely distended, but no stones could be detected. After vain efforts to empty the gall-bladder by well-directed pressure, it was found that there was some inflammatory obstruction about the common duct. The gall-bladder was aspirated and emptied. After incising it an effort was made to pass a probe through the duct into the intestine, but it could not be accomplished. The operation was completed in the ordinary way, and the gall-bladder washed with warm water twice daily. On the sixth day a large plug of inspissated bile was washed out, which was believed to come from the common duct, and after that time much less bile came from the gall-bladder. She made a rapid recovery and is now enjoying good health, yet she has a fistulous opening which discharges a very small quantity of bile, but this does not appear to interfere with her general health The stools are of the natural color, and she has regained her usual weight and strength.

Case V.—Mrs. R——, Covington, O., aged thirty-nine, had been subject to sudden and severe attacks of pain in the hepatic region for seven or eight years, and a number of times had a distinct enlargement in the region of the gall-bladder during, and after, attacks of pain. Nine weeks before my first visit, June 11, 1892, after a severe attack of several days' duration, she became jaundiced, and remained so until the time of my visit, when the cholæmia was extreme. The patient was in a dazed condition and did not notice anyone about her unless spoken to; the pulse was 128, temperature, 98° F. The liver was enlarged, the lower border was easily defined about three inches below the ribs. A distinct enlargement could be made out to the right of the liver, which was supposed to be the gall-bladder. She vomited some mucus every little while. A diagnosis of obstruction of the common duct was made, and an operation was advised. This was done at the patient's home, June 15, 1892, with the assistance of Drs. Harrison, Schoffield, Templeton, of Covington, and Frame, of Piqua, O. When the abdomen was opened the gall-bladder was found to be largely distended and containing a number of gall-stones. It was aspirated and incised, and seventy-five gall-stones, varying in size from that of a pea to a cherry, were removed. The cause of the obstruction was found to be a stone in the common duct, which could not be removed through the gall-bladder or pressed on into the intestine, owing to some inflammatory exudation. It was plainly evident that to leave the stone would leave the common duct obstructed for all time, and that there would constantly be a fistulous opening if the patient recovered; therefore I removed it by incising the common duct. Before this could be done, however, I was obliged to enlarge the abdominal incision, which I did by extending it upward and to the left, along the border of the ribs, to a point a little past the median line, making a kind of a flap of the abdominal wall. With this turned back we had ample room for work, and the duct was incised and the stone removed. I at once closed the opening in the duct with catgut suture, and packed a strip of gauze under and around the duct, bringing the end out at the upper part of the wound, where three stitches were left untied. The gall-bladder was stitched to the abdominal wound in the usual manner, and drained The patient remained in the same dazed condition as before the operation, with no indication of improvement. She had no rise of temperature, and died from exhaustion June 17th, fifty-three hours after the operation. I do not think the incision into the common duct made her chances for recovery any less, as there was no leakage from it. But the fatal error was that the operation was deferred until the patient was in a dying condition. Here again we see the necessity of an exploratory incision in these obscure hepatic difficulties. This patient had been a subject of gall-stones for years, and if she had been operated upon before the common duct was obstructed, while she was yet in good physical condition, before the profound cholæmia of her last illness, I have but little doubt that she

would have recovered. With the light of my present experience, I would hesitate to operate upon any patient who had suffered from complete obstruction of the common duct for so long a period of time. The powers of recuperation are so feeble that we can hardly hope for other than a fatal termination.

Case VI.—Miss H——, aged twenty-four, sick for twenty months with indigestion and pain in the region of the stomach and liver. Three weeks before my first visit she went to bed with some form of continued fever, which her physician, Dr. Juettner, of this city, could not define. She grew gradually worse, with a fluctuating temperature and pulse. On the day preceding my visit her physician discovered a swelling in the region of the gall-bladder, which was exceedingly sensitive to pressure. On June 18, 1892, I saw the case with her physician. She had a pulse of 120; temperature, 103° F. The liver was enlarged, and there was a distinct swelling in the region of the gall-bladder, but she had no jaundice. I had no hesitation in pronouncing the swelling to be the distended gall-bladder, with probably suppuration, and advised an operation at once. The patient was sent to the Presbyterian Hospital, where I performed the operation the following morning, removing sixteen ounces of pus and thirteen gall-stones from the gall-bladder, the largest of which was firmly impacted in the cystic duct. The patient recovered without incident, and went home twenty-six days after the operation.

Case VII.—Mrs. B——, aged forty-two, Bainbridge, O., referred to me by her physician, Dr. McKee, July 12, 1892, with the following history: Twenty years ago she had a severe attack of pain in the region of the liver, which continued for forty-eight hours; this was repeated on two subsequent occasions, at intervals of about one year each. After that time she had only slight uneasy sensation in the right side and stomach until fourteen years ago, when she suffered from the fourth severe attack of pain, which continued for several days. After this attack she was rarely free from pain for a week at a time, yet she had only a few very severe attacks until five years ago. But for the past five years she has been under the care of her physician most of the time. For more than a year before she came to me, there had been a distinct enlargement to the right of the enlarged liver. She suffered terrific attacks of pain brought on by the least exertion. I had no hesitation in pronouncing the case one of gall-stone, and advised an operation, which was done at my private hospital July 15th, and three stones as large as the first joint of a man's thumb, and one hundred and thirty-five stones varying in size from a grain of wheat to a bean, were removed. The patient developed a severe hepatitis after the operation, and on the fourth and fifth days was alarmingly ill, but after that she made an easy and complete recovery.

The cases reported are duplicates of hundreds of patients suffering from obscure pain in the hepatic region. It will only be necessary to demonstrate to the profession at large the importance of operation upon these chronic cases before the common duct is obstructed, to gain their co-operation, and thus save years of untold suffering and many valuable lives, which would otherwise be lost. If all of the cases operated upon where the common duct was obstructed could be tabulated, the mortality would probably be very great. On the other hand, after operation for gall-stones where the common duct is not obstructed, the mortality is not more than two or three per cent. in the hands of men prepared to do this work. These facts alone, if no other could be advanced should be sufficient to warrant early operations, and, if the theory be correct that the long-continued irritation of pent-up gall-stones acts as an exciting or predisposing cause of malignant disease, in or about the gall-ducts, this is the greatest reason of all for advising exploration in all doubtful and obscure cases of chronic hepatic difficulties, and early exploration in all cases of distended gall-bladder.

15 West Eighth Street.

FIFTY SELECTED CASES FROM THE PRACTICE OF DR. CLEMENT CLEVELAND AT THE WOMAN'S HOSPITAL OF THE STATE OF NEW YORK.

By LeRoy Broun, M.D.,

Assistant Surgeon to the Woman's Hospital, New York.

These cases have been selected from the practice of Dr. Cleveland at the Woman's Hospital, and the object of bringing them together is that the majority are of interest and, to the writer at least, instructive. Before taking up the several classes a *résumé* of the general technique carried out will be given in brief. This has necessarily varied in the last two years; that as exercised at present is as follows:

Cleansing Abdomen.—This is done thoroughly the night before the operation, if possible, and a wet bichloride towel or gauze kept on over night. At the time of the operation it is cleansed again with soap and water, then with ether and alcohol, and finally with bichloride solution. In vaginal operations the vagina is thoroughly scrubbed with soap and a soft brush, irrigated with water and afterward with a bichloride solution.

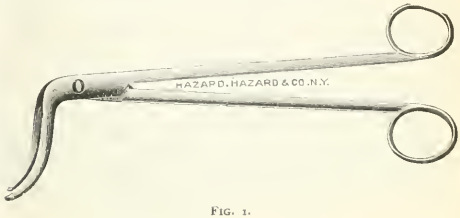

Fig. 1.

The Hands.—It has been determined that after immersion in a strong bichloride solution the scrapings from under the nails would yet yield bacteriological cultures. After immersion in a saturated solution of permanganate

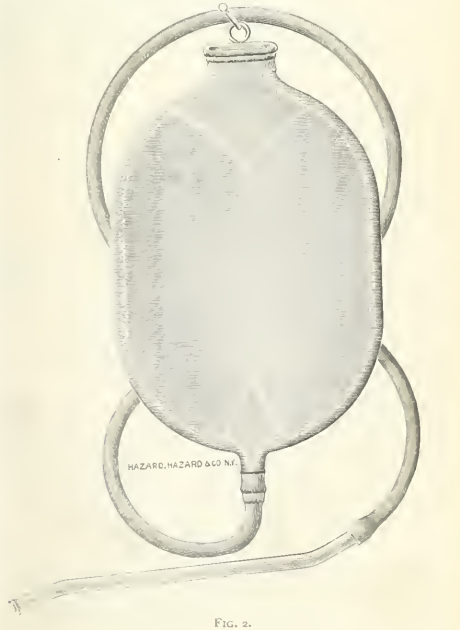

Fig. 2.

of potash and a subsequent bleaching by oxalic acid, the scrapings were sterile. Since this determination it has been the habit of Dr. Cleveland to require all con-

cerned in the operation to exercise this rigid care in cleansing.

Towels, Gowns, etc.—These are all sterilized for one hour before operation. In private practice, when this cannot be done, the towels are wet in bichloride solution 1 to 1,000.

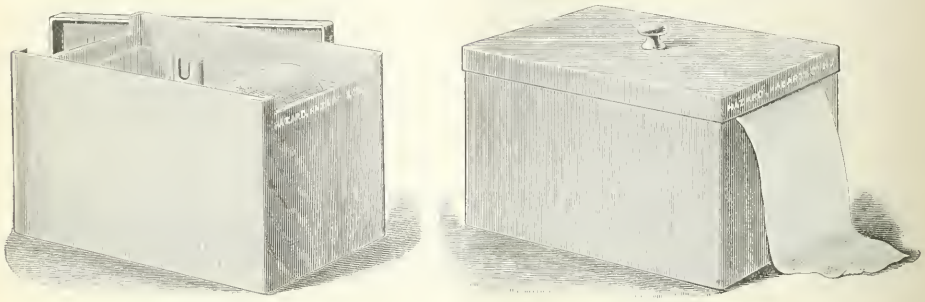

Fig. 3.

Ligature Passer.—For tying off pedicles and transfixing stumps a forceps devised by Dr. Cleveland is in use. This is illustrated in Fig. 1.

Being pushed through the pedicle it is slightly opened; the ligature, held by an assistant, is grasped and the instrument pulled back, or *vice versa*. For ease of handling and rapidity of work it is much superior to the aneurism needle ordinarily used for such purposes.

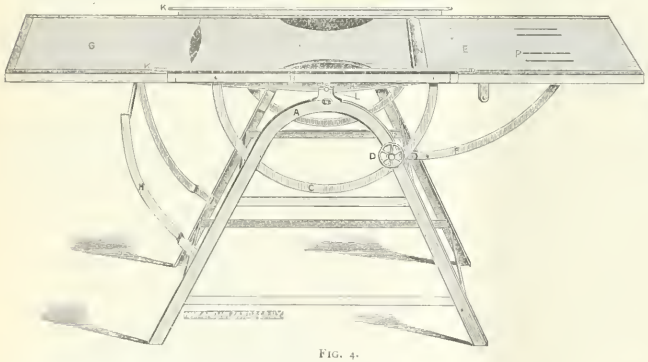

Fig. 4.

Irrigator.—For use in private practice I have had made by the Alpha Company a rubber bag of one gallon capacity, with a half inch outlet. This, together with its accompanying tube, is always boiled before use. Fig. 2 gives the irrigator and glass tube attached. The engraver has by some mishap represented the wrong end of the glass tube inserted into the tubing.

Sterilized Gauze.—For furnishing sterilized gauze for peritoneal drainage, or vaginal packing after a hysterectomy, this box, as shown in Fig. 3, was devised by the writer especially for use in private practice. It is made of block tin, is 6 inches long, $3\frac{1}{2}$ inches wide, and $3\frac{1}{2}$ inches deep. It is provided with a snugly-fitting top of the same material. From each end there is cut a slot wide enough to allow a two and a half inch strip of gauze to pass through freely. Inside is placed a smaller metal case so arranged as to support two glass rods, over which each roll of gauze revolves. In using this box the gauze rolls, which have been previously prepared, are put in place, the cover placed on, and the whole sterilized for one hour. It is then wrapped in towels which were sterilized at the same time. Thus protected the box is not disturbed until desired for use during the operation.

In this way the gauze is not touched except at the operation, and then only by the operator. Again its atmosphere is practically sterile until needed. If iodoform gauze is used care should be taken that the free ends of the rolls do not lie upon the bottom of the box, for if they do this part will be changed to the blue color due to the decomposition of the iodoform.

Operating Table.—For the last year there has been in use a table devised by Dr. Cleveland, its object being to furnish Trendelenberg's position whenever desired.

The cuts of the table as here shown and its rapid sale by the maker will render an explanation of its working almost useless, yet a few words as to some of its special features will not be amiss. When the table is thrown into the inclined position (Figs. 4 and 5), the knees are elevated by the foot-piece above the plane of the abdomen. In this position the recti and psoas muscles are relaxed and work is facilitated.

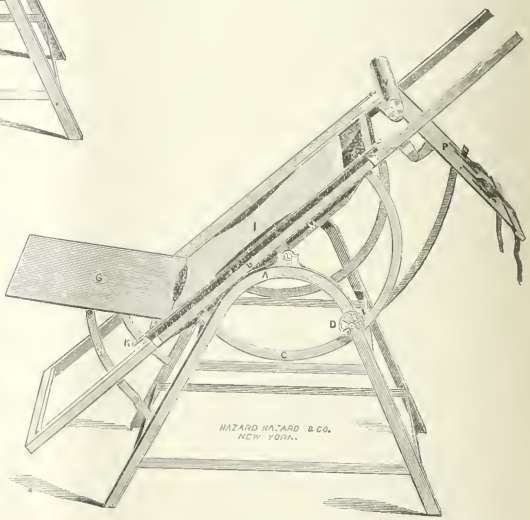

Fig. 5.

The table is made of angle iron and is as light as is compatible with strength. The top can be moved from its frame with ease, and, being in sections, can be readily cleaned.

Ligatures.—For the last two years a large catgut, No. 6 to 8, has been used for tying off pedicles and has given excellent satisfaction. This is rendered sterile by immersing the raw gut for one hour in ether to free it of its oil, then for twenty-four hours in a watery bichloride solution, 1 to 1,000. It is then kept in pure alcohol which is changed until the gut is hardened. Thus prepared the gut has given no cultures even from its centre.

Catheterization.—It is the experience of all who had the after-care of operative cases to be much annoyed by vesical irritation and a possible cystitis following the careless use of the soft-rubber catheter. For the last two years this has been reduced to a minimum by the use of a glass catheter, which is kept scrupulously clean by boiling and being kept in bichloride solution. Before its use the vulva is thoroughly washed off with warm water and afterward with a weak bichloride solution. The catheter first in use was one with a closed end and side holes. After some time a sediment was always found at the closed end. This was difficult to remove. To remedy this a catheter as represented in Fig. 7 is now in use and gives excellent satisfaction.

These I have had made by Emil Greiner, of 146 William Street, at a cost of about six cents a piece.

Cysts.—The location of these cysts bear out, in an interesting manner, the fact established that it is more frequent that the right side is affected. Out of 349 cases collected by Safford Lee and others 173 were upon the right side and 126 on the left. Of these cases reported—putting aside four, of which two were double, and two of broad ligament origin—we have eight as recurring on the right side and four on the left.

FIG. 6.

Cysts.

No.	Date.	Name.	Age.	Social condition.	Nature of cyst.	Adhesions.	Recovered.	Died.	Pathological report.
1	February 24, 1890.	Mrs. H. T.	31	Married.	Ovarian cyst of left side.	To parietal peritoneum and intestines.	Yes.	....	Monocular cyst.
2	April 21, 1890.	Mrs. E. B.	24	Married.	Ovarian, right side.	.....	Yes.	...	Multilocular cyst, seventy centimetres circumference.
3	September 22, 1890.	Miss J. F.	23	Single.	Cyst of broad ligament.	.....	Yes.		
4	October 6, 1890.	Mrs. M. L.	30	Married.	Ovarian, right side.	.....	Yes.		
5	October 13, 1890.	Miss K. K.	48	Single.	Ovarian, right side.	.....	Yes.	....	Multilocular cyst.
6	November 3, 1890.	Mrs. A. J.	34	Married.	Ovarian, right side.	.....	Yes.	...	Monocular cyst.
7	May 11, 1891.	Mrs. L.	31	Married.	Cyst of broad ligament.	.....	Yes.		
8	October 14, 1891.	Mrs. M. R.	77	Married.	Ovarian, double; larger of left ovary.	.....	Yes.		
9	October 24, 1891.	Mrs. H. P.	47	Married.	Ovarian, right.	.....	Yes.	....	Cyst adenoma.
10	January 30, 1892.	Miss E. F.	23	Single.	Ovarian, right side.	.....	Yes.	....	Multilocular cyst.
11	February 1, 1892.	Miss K. F.	43	Single.	Ovarian, left side.	.....	Yes.	....	Multilocular cyst.
12	May 9, 1892.	Mrs. K.	38	Married.	Ovarian, right side.	.....	Yes.		
13	February 9, 1891.	Mrs. I. S.	32	Married.	Ovarian, double; larger left side.	.....	Yes.	....	Multilocular cyst.
14	.....	Mrs. R. G.	37	Married.	Suppurating cyst of right ovary; tubercular salpingitis left.	.....	Yes.	...	Tubercular salpingitis confined to mucous membrane of tube; ovarian cyst with suppurating wall.
15	June 3.	Mrs. G.	42	Married.	Papillary cyst, left.	Slight.	Yes.	....	Section through cyst-wall shows interior of wall well covered with papillary growths.
16	June 7.	Mrs. A. H.	48	Married.	Cyst of left ovary.	None.	Yes.	...	Diagnosis, unilocular papillary cyst of the ovary.

Age.—The time of life among these patients is that in which we generally expect to find cystic development. The advanced age of one, Mrs. M. R——, is unusual. She presented herself for operation at the age of seventy-seven. Both ovaries had been transformed into cysts, of which the left was predominant. Her recovery from the operation was uneventful. Three weeks after she contracted a double pneumonia and died.

Menstruation.—This function, where the menopause had not already come about, was, when disturbed, increased in amount rather than otherwise. With four of the cases the cysts were first noticed after the menopause, with three menstruation was in no way disturbed. With three others the time of the flow was increased and with one of them constant. In the instance of the first mentioned patient in this list the menstrual history is of especial interest. At the operation in September, 1890, a large cyst of the left side was removed. The right ovary and tube being normal was not disturbed. She is now in the hospital for the removal of a large cyst of the remaining ovary (right). Her menstruation at the time of the existence of the first cyst was of the twenty-eight day type and nine days' duration. For the last two years it has not been disturbed; evidently the ovarian tissue was not all obliterated by the large cyst of the remaining ovary. At the section, done the day of this writing, the stump of the former operation was raised up and examined with care. No remains of the silk ligature used existed. A small cicatrix of slightly darker hue than that of the surrounding parts was all that remained of where the ligature once existed.

Mural Abscess.—One of the patients (Case VI.) had a mural abscess following the removal of a soiled stitch. This healed promptly. She returned a year later for the closure of a ventral hernia over the spot. In the instance

of the case last upon the list, the interior of the cyst-wall was covered with small papillary growths. Some of the contents escaped during its removal into the general peritoneal cavity; this was removed as much as possible by irrigation. The patient is being watched with care for any secondary growths that may spring up from this escape of fluid.

Pyosalpinx.—Case I. was a sub-peritoneal abscess, probably from a breaking down hematocele, if such exists. It had been discharging into the rectum for some weeks. Its contents were evacuated by a trocar and its cavity well washed out. The edges of the sac were stitched to the abdominal wound and drainage established by tube and gauze. The rectal opening closed and gradually the sinus was obliterated.

Ventral Fixations.

No.	Date.	Name.	Age.	Social condition.	Local condition.	Method of operation.	Drain.	Recovered.	Died.	Pathological report.
1	November 22, 1889.	Miss K. F.	32	Single.	Retroflexion, fixation; catarrhal salpingitis and follicular cysts.	Salpingo-oöphorectomy. Uterus fixed anteriorly, one stout silk ligature passing through abdominal wall and body of uterus.	....	Yes.	....	Catarrhal salpingitis; follicular cysts.
2	February 10, 1890.	Mrs. M. B.	32	Married.	Complete procidentia; chronic salpingitis.	Salpingo-oöphorectomy. Uterus fixed anteriorly, buried silk sutures taking in fascia, peritoneum, and adjacent stump and horn of uterus.	....	Yes.	....	Chronic ovaritis and hyperplasia tubes.
3	March 31, 1890.	Mrs. C. D.	36	Married.	Retroversion; fixation; salpingo-oöphoritis, chronic.	As in Case No. 2.	....	Yes.	....	Chronic ovaritis with follicular cysts.
4	October 23, 1891.	Miss L. M.	39	Single.	Retroversion; fixation; hæmatoma, both ovaries; chronic salpingitis.	Salpingo-oöphorectomy. Ventral fixation as above, No. 2.	....	Yes.	....	Both ovaries converted into single cysts, into which had been hemorrhage, tubes, hyperplasia, and catarrhal salpingitis.
5	.....	Miss A. C.	30	Single.	Retroversion; fixation; large uterus.	Catgut used as ligature, being passd through ovarian ligament and adjacent fascia and peritoneum.[1]	....	Yes.		
6	February 13, 1892.	Miss M. R.	19	Single.	Retroversion; fixation; cystic left ovary.	Removal of diseased ovary and tube, left. Body of uterus scarified anteriorly. Sutures, two, passed through abdominal wall and body of uterus.	....	Yes.	....	Chronic ovaritis, with follicular cysts; tube hyperplasia with catarrhal salpingitis.

[1] Done by Dr. Klitzsch.

Ventral Fixations.—Some of these cases are of too recent a date to speak with any definite assurance of the result, yet all have been relieved of the symptoms for which the operation was done. The first four cases have been seen within the last month, and in each the uterus was in position, and the patient relieved of her pressure symptoms. The method used in the last case is the one most preferred by Dr. Cleveland; certainly by it a large area of coaptation is obtained between the uterus and the parietal peritoneum. When the appendages have been removed it was on account of a cystic degeneration of the ovaries, together with a thickening of the tubes.

Case II. is of interest in exemplifying how at times it is difficult to map out tubal trouble. She was a strong German working-woman, in excellent health to all appearance; she complained constantly of pelvic pains. The local condition gave only a retro-displaced uterus partially held by a few firm bands. Not being able to retain the organ in position by a pessary ventral fixation was suggested. She was under treatment for two months before the abdominal fixation was considered. During this time she was seen four or five times a week by the visiting surgeon or house surgeon. Before the operation was done she was examined by two other surgeons, as is the custom,

Pyosalpinx.

No.	Date.	Name.	Age.	Social condition.	Local condition and operation.	Drain.	Recovered.	Died.	Pathological report.
1	November 25, 1889.	Mrs. A. C.	29	Married.	Edges of sac stitched to abdominal wound.	Yes.	Yes.		
2	December 2, 1889.	Miss M. K.	22	Single.	Double. Removal of both.	.....	Yes.	.....	Chronic suppurative salpingitis.
3	December 20, 1889.	Mrs. E. H.	29	Married.	Double. Removal of both.	Yes.	.....	Yes; April 24, 1890.	Suppurating salpingitis. Measurements: larger tube, 14 ctm. long, 7 ctm. thick, and 6½ ctm. wide; larger end, 21 ctm.; smaller end, 17 ctm.; longitudinal circumference, 32 ctm. No gonococci. The smaller one was too thin walled to distend for measurement.
4	January 31, 1890.	Miss C. J.	19	Single.	Double; gonorrhœal. Removal.	.....	Yes.		
5	November 29, 1889.	Mrs. K. S.	31	Married.	Double. Removal of both.	.....	Yes.		
6	February 17, 1890.	Mrs. A. R.	23	Married.	Pyosalpinx and cyst of one ovary.	.....	Yes.	.....	Chronic ovaritis with small amount of ovarian tissue remaining. Tubes show hyperplasia, and distal end of one is infiltrated with pus.
7	February 23, 1891.	Mrs. S.	..	Married.	Pyosalpinx; double.	.....	Yes.	.....	Suppurating salpingitis.
8	March 9, 1891.	Miss C. G.	21	Single.	Pyosalpinx, left, and intraligamentous cyst, left. Removal and resection of five inches of intestine.	Gauze and tube.	Yes.		
9	May 21, 1891.	Mrs. P. D.	31	Married.	Pyosalpinx; double. Removal.	Yes.	.....	Yes.	Suppurating double salpingitis with suppurating ovarian cysts.
10	January 9, 1892.	Mrs. L. S.	26	Married.	Pyosalpinx, left. Removal.	Yes.	Yes.		
11	February 6, 1892.	Mrs. M. B.	22	Married.	Pyosalpinx; retroversion; fixation. Removal.	....	Yes.	.....	Left: ovary a thin walled cyst; tube, suppurating salpingitis. Right: advanced chronic ovaritis; tube, marked hyperplasia of uterine end with catarrhal salpingitis. *a.* Suppurating ovaritis with suppurating salpingitis. *b.* Chronic ovaritis with hyperplasia and catarrhal salpingitis; small parovarian cyst.
12	February 8, 1892.	Mrs. M. M.	38	Married.	Abscess of ovary; pyosalpinx; parovarian cyst. Removal.	.....	Yes.		

and in no case was any condition excepting a retroverted uterus, partially fixed, discovered. The operation gave this condition with both tubes much distended with pus. These were high up and out of reach of the vaginal finger. The woman being full fleshed and the abdomen tense they could not be detected by the external hand.

Case III.—This case is remarkable for the immense size of the tubes. The measurements are given under the pathological report. Her recovery was uninterrupted as concerned the immediate operation. The cause of death was exhaustion from an abscess around the pedicle.

Case IV.—This case shows in a clear manner how rapid gonorrhœal infection can be. The patient contracted the disease about Christmas, 1889. She was admitted to the hospital January 2d, when, in addition to the severe vaginitis, tubal distention had already begun.

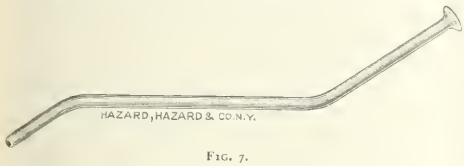

Fig. 7.

Case VIII.—Here the adhesions were of such a dense character that it was with considerable difficulty the cyst and diseased appendix could be liberated. The tube was attached to the sigmoid flexure and in liberating an angular rent was made in the gut an inch and a quarter long. The serous covering was also stripped up for five inches. The injured portion had such an unhealthy appearance that it was thought wise to resect the five inches and do a circular enterorrhaphy. This was done, iron-dyed silk being used. The cavity was then packed with gauze, bringing it up through the abdomen for drainage. Morphine was used to quiet peristalsis, and no movement of bowels until the eighth day allowed. Recovery was uninterrupted, a sinus being left which healed at an early date.

Case IX.—When this patient was admitted to Dr. Cleveland's service the entire pelvis was filled up with an unyielding exudation. She was having a nightly rise of temperature of one or two degrees. At one time while in this condition the temperature reached 107° F. Since nothing could be done by operation, thirty grains of calomel was given, with the happy effect of the temperature falling to almost normal and remaining so for about a week. The local condition was also much improved. The exudation clearing up to a considerable extent, an effort was made to remove the purulent foci. Adhesions were dense. These were broken, and distended tubes on both sides were removed with their ovaries. The pelvis was packed with gauze for drainage. The patient did well. She was seen the second night with a good strong pulse. She died a few hours after. No autopsy was allowed, and the cause of death was not known.

The other cases reported here are of interest in various ways. Taking them as a class, wherever drainage has been necessary gauze has been used packed in a solid column from the bottom of the pelvis into the abdominal wound. Where intractable sinuses have been left they have been, where feasible, opened into the vagina by means of a trocar and cannula, and after establishment of drainage they have closed without trouble.

Unclassified Cases.—Case I.—It was much regretted that this specimen was lost, for of its benign or malignant character nothing can be said. These solid tumors of the ovary are generally malignant. Those of a myomatous type being rare. Doran states that he has never seen a pure fibro-myoma of the ovary removed, but finds one in the museum of the Royal College of Surgeons. Tait states that he removed four, and gives some data from other writers.

Unclassified Cases.

No.	Date.	Name.	Age.	Social condition	Disease.	Operation.	Drain.	Recovered.	Died.	Pathological report.
1	October 21, 1889.	Miss M. B.	29	Single.	Solid tumor of right ovary.	Removal.	....	Yes.	....	Specimen lost.
2	March 21, 1892.	Mrs. G.	26	Married.	Fibro-adenoma of parovarium.	Removal.	....	Yes.	....	Fibro-adenoma of parovarium.
3	February 10, 1890.	Mrs. B. R.	27	Married.	Hydrosalpinx right side.	Removal of both appendages, the left tube being thickened and ovary with follicular cysts.	....	Yes.	....	The hydrosalpinx of right tube measures 5½ ctm. longest diameter, and 3¼ ctm. shortest diameter.
4	March 16, 1892.	Mr. W.	23	Married.	Hydrosalpinx, double.	Removal of both; left ovary was allowed to remain.	...	Yes.		
5	March 2, 1891.	Mrs. M. B.	..	.....	Tubercular peritonitis.	Opening and drainage.	Yes.	Yes.		
6	.....	Mrs. B.	22	Married.	Tubercular peritonitis.	Opening without drainage.	....	Yes.		
7	May 20, 1891.	Mrs. M. H.	38	Married.	Umbilical hernia; adhesions; irreducible.	Dissection anteriorly and removal of adherent omentum.	....	Yes.		
8	October, 1892.	Mrs. A. J.	34	Married.	Ventral hernia, as result of mural abscess following section one year ago.	Closure by method suggested by Dr. Pryor.	....	Yes.		
9	May 18, 1891.	Mrs. M. K.	26	Married.	Pyonephrosis.	Lumbar opening and evacuation of pus.	....	Yes.		
10	November 15, 1888.	Mrs. E. D.	28	Single.	Pyonephrosis, large.	Abdominal section; evacuation through trocar and stitching of sac to abdominal wall.	....	Yes.		
11	December 7, 1891.	Mrs. H. M.	31	Married.	Cystic papilloma of mesentery; ascites.	Exploratory and removal of portion for diagnostic purposes.	....	...	Yes.	Cystic papilloma of omentum.
12	January 18, 1892.	Miss A.	29	Single.	Papilloma, both ovaries.	Removal.	....	Yes.	....	Papilloma of both ovaries, each mass springing from its ovary by three distinct fibrous pedicles. See fuller report in remarks.
13	January 9, 1891.	Miss D.	55	Single.	Fibroid in folds of left broad ligament.	Enucleation with hysterectomy.	....	....	Yes, 9 days after.	
14	November 30, 1891.	Miss S. M.	30	Single.	Mass to right of uterus.	Exploratory operation; mass proved to be a pedunculated fibroid.	....	Yes.		
15	April 18, 1892.	Mrs. C.	44	Married.	Adhesions.	Section; few broken up; closure.	....	Yes.		
16	January 12, 1891.	Mrs. L. J.	29	Married.	Varicocele of right broad ligament.	Section; removal of both appendages with ligature of pampiniform plexus.	....	Yes.	....	One ovary converted into a cyst filled with blood, the other having a small number of cysts. Tubes, catarrhal salpingitis.
17	June 8, 1892.	Mrs. H.	34	Married.	Tubal pregnancy.	Removal of sac and blood-clots.	Yes.	Yes.		

Case II.—This case is of unusual interest on account of the rare occurrence of such a condition. Her history, given in brief, is one of uncontrollable menorrhagia. She was curetted at various times without any diminution in the amount of the flow. The presence of the solid tumor of the right side was always recognized, yet its removal put aside as a last resort. There was no ascitic fluid in the cavity. The part of the annexa involved its fibro-adenomatous character, the absence of any fibroid growths in connection with the uterus, with absence of ascites, makes this case one of marked interest. I have not been able to find in the literature consulted a statement of a similar occurrence. I give the entire pathological report of Dr. George C. Freeborn, pathologist of the hospital, and by whom examinations of all the other specimens in this report have been made.

Macroscopic.—The ovary is a semi-ovoid shaped mass 7½ ctm. in its long diameter and 6 ctm. in its shorter. Section shows a solid white tumor enclosed in a thin, fibrous capsule. At the outer and lower end of the tumor is a semilunar-shaped mass, 3 ctm. long and 1½ ctm. thick, composed of tissue resembling that of the ovary. The elongated tube is attached to the upper surface of the mass.

Microscopic.—Shows compressed ovary attached to one side of the tumor, and separated from it by a thin layer of fibrous nature. The tumor proved to be a fibro-adenoma of the parovarium.

Cases III. and VI. were of the typical tubercular class with the characteristic nodules scattered over the viscera; one was treated with drainage, the other without. The one without drainage has been of such recent date that nothing can be said definitely as to the result. She will be watched with interest to know whether there will be a recurrence of the effusion. The reason of omitting drainage in this case was the presence of a tuberculous spot in the apex of one lung.

Case VII.—This case was operated on for a cure of the hernia at her earnest request. It was of omental character which was closely adherent through the entire circumference of the ring which was of a hard cartilaginous nature. That portion of omentum protruding through this cicatricial umbilical opening was a mass of small fibrous nodules, probably inflammatory in origin, scattered through what remained of the omental tissue.

Case VIII.—This case is chiefly of interest in that the hernia followed a mural abscess of one year before, at which time she was in the hospital for the removal of an ovarian cyst. The hernia was closed after the method suggested by Dr. Pryor for closure of the abdominal wound following laparotomy, that is, the peritoneum and transversalis fascia were brought together by fine catgut, the muscle and its sheath by an independent layer of sutures of fine silk, and the remaining portion allowed to granulate up.

Cases IX. and X.—These cases are examples of conservatism, both abscesses of the pelvis of the kidney, in both opening and drainage, one by the abdomen and afterward a counter-opening made in the side, the other in the lumbar region. Both recovered, and are in excellent health.

It is true that in both cases the recovery was prolonged and required watchful care, yet they recovered, which is by no means so certain if the kidney had been removed in both cases. In general it is recognized that the history of these cases is that the affected kidney atrophies and ceases to excrete urine, hence there is no cause to look for a recurrence. The cause of the abscess was not found in either case.

Case XI.—This case is of unusual interest, as it appears to mark the extension of a cystic papilloma from the ovaries and tubes to the omentum. The patient was enormously distended, and was becoming more so rapidly. The diagnosis of ascites with malignancy was made. Laparotomy, ascitic fluid liberated. The omentum was converted into a mass of small cysts, varying in size from a pea to that of a walnut. It was adherent to the pubic arch, uterus, and intestines. Both ovaries were cystic and both tubes enormously distended. The cysts were filled with a clear fluid. A portion of the omentum was cut away for diagnostic purposes.

Pathological report, cystic papilloma of omentum. The patient died soon after operation, of exhaustion.

Dr. Cleveland tells me that it is the opinion of the pathologist that the disease undoubtedly started in the ovary and extended from there to the omentum and tube.

Case XII.—This, one of papilloma of both ovaries, shows, in a beautiful manner, the proliferation of this new growth, and in describing the case I draw from the report of Dr. Cleveland before the Obstetrical Society and the discussion following. Speaking of the operation he says:

"When the ascitic fluid was withdrawn the cavity was fairly opened, and an ovarian cyst surrounded by a papillomatous growth was found on either side. In removing the mass from the left side much difficulty was experienced from the dense mass of adhesions that held it down. After its removal examination disclosed the peritoneum at the bottom of the pelvic cavity covered with small projections that felt like small shot adhering to the surface. This was the only spot in the whole abdominal cavity which showed the extension of the disease beyond the ovaries. The whole pelvic cavity at this point was a vast oozing surface, and was packed with a solid column of gauze—over twenty yards being used—not merely to stop the oozing, but in the hopes that in some way it might limit the disease or shut it off from the general abdominal cavity; that possibly the pressure alone would not only stop the bleeding but check the proliferation that had evidently commenced on the peritoneal surface at this point."

At this writing Dr. Cleveland tells me that he has seen this patient within the last few days. She is in excellent health, having gained flesh, and there is no recurrence of her trouble. He is of the opinion that when met with at such an early stage, papilloma lacks that malignancy of which it partakes later. Either this, or clinically, there are two classes of these growths, one more malignant than the other.

Pathological Report.—The right cyst is thin-walled and grows from one side of the ovary. Projecting into the interior of the cyst from one side is a lobulated cauliflower-like mass which appears to be connected with a similar mass on the outside of the cyst-wall. The remains of the ovary is imbedded in the mass of new growth. This growth springs from the ovary by three distinct fibrous pedicles forming three distinct lobules.

The left is an irregular trilobed cauliflower mass. Longitudinal section shows an elongated ovary imbedded in the centre of the mass. The new growth springs from the ovary by three distinct pedicles.

Case XIII.—This case is one of a fibroid the size of a fœtal head in the folds of the left broad ligament. The mass was entirely independent of the uterus in a capsule of its own. Doran and Pozzi both state that these may come originally from the uterus and afterward become independent; or may develop *de novo* within the folds of the ligament.

This case calls to mind a similar one occurring in the private practice of Dr. Cleveland and not reported here, where the tumor was within the folds of the ligament and entirely separate from the uterus, being easily shelled out. This was a fibro-myoma as reported by the pathologist. Neither in the case reported nor in the other were there any fibroids connected with the uterus.

It was found necessary to remove the uterus with the tumor. The patient died on the ninth day of sepsis, doing well up to the seventh.

Case XIV.—This case is reported on account of such a condition introducing a possible error in the diagnosis of even a skilled diagnostician. This mass to the right of

the uterus was made out distinct from the uterus and not moving with it. The history of a pyosalpinx was made out. The mass was sensitive to touch.

Laparotomy. Mass proved to be a pedunculated fibroid. Not removed and abdomen closed.

Case XVI.—This case is of interest on account of prompt relief given by operation and history. She was in perfect health with no pain at menstruation up to five months before operation. At this time while menstruating she experienced a sharp pain over the left side, attended by sudden cessation. The pain lasted for one week and was very severe. With each following period she experienced such pain for the week before the advent of the flow that only large doses of morphia would relieve her. The flow established, all pain would vanish.

She passed the November period in the hospital and I saw that she suffered excessively. At other times she was perfectly quiet. The varicose condition being relieved and nothing abnormal found she was discharged.

December 7th she again entered the hospital, begging for an operation and saying that the pain was as severe as before.

Laparotomy. Removal of appendages.

Pathological Report (*abbreviated*).—One ovary converted into a cyst filled with blood, the other having a number of small blood-cysts.

Tubes, catarrhal salpingitis. Here we have an apoplexy, so to speak, of both ovaries. It seems to me that her intense pain before the period and relief when it was established is explained by this data—on the ground of the extra congestion of and pressure from within upon these organs before the period and relief from this at the period.

She was thoroughly relieved by the operation.

THE SURGICAL TREATMENT OF ACUTE ARTHRITIS OF THE HIP IN INFANTS.[1]

With Presentation of Two Cases Fully Recovered.

By VIRGIL P. GIBNEY, M.D.,

New York.

A few days ago, at the request of Dr. Bull, who was billed for a paper on this occasion, I consented to present a short paper, as it was impossible for him to keep his appointment this evening. I gave the Secretary the above title in order to bring out in striking relief what I considered to be the best treatment of acute arthritis of the hip in infants.

The subject of acute arthritis has been treated by various authors, such as Terrisse in France, T. Smith in London, Barwell, Krause, Macnamara, Wright, Howard Marsh, W. R. Townsend, and the reader of the present communication.

My own observations extend over a period of twelve or fifteen years, but it is only in recent years that I have felt equal to the proper management of the case so that life might be saved and deformity prevented. The disease is essentially one of early life, occurring during the first twelve months of life as a rule, is very active in its progress, is destructive of the structures immediately entering into the formation of the joint, and often of the bony structures. It is caused by one of the forms of staphylococci. The mortality is about fifty per cent. Where recovery does take place, the rule is to have a weak, flail-like joint, and it is not uncommon to find conditions very similar to that of congenital dislocation of the hip. From one of the more recent papers on this subject, by Dr. W. R. Townsend, and published in the "Transactions of the American Orthopedic Association for 1889," I have taken all the cases wherein the hips were involved, and of seventy-one cases in his table, thirty-three affected the hip-joint or joints. Of these thirty-three seventeen are reported as dying from the disease, sixteen as recovering.

The stereotyped method of treatment formerly was to incise the abscess, drain, and get healing as quickly as possible. The sixteen cases that recovered did not all recover with perfect joints. I am at a loss, this evening, to state just how many of this number did recover with perfect joints, but my impression is that the number is very small.

The cases I have to present this evening show unusually good results, I think, for clinic cases, and I believe a good functional result is due to the care taken in immobilizing the parts during the reparative process and maintaining all the time the parallelism and equal length of the limbs. The reports are as follows:

Case I.—Ida L——, aged ten months, presented at my clinic on May 28, 1892, suffering from an acute abscess which completely encircled the left hip. The child was greatly emaciated, suffered intensely, and was exceedingly irritable. The father's name was H—— L——, living in Madison Street, first floor front.

Ether was given, the abscess completely opened, front and back, thick cheesy material, containing a lot of pus, two ounces in quantity, removed, the finger inserted and joint found to be not involved. It was, therefore, a periarticular abscess. The cavity was curetted, washed thoroughly with sublimate, 1 to 1.000, packed with iodoformized gauze, the deformity fully corrected, full dressing applied, and plaster of Paris applied from the foot up over the hip and body to the axilla. There was a second focus of disease at the right wrist. This was opened and dressed in the usual way. Patient sent home in mother's arms.

September 7th.—The child attended the clinic regularly about once a week until the early part of the summer, when the wounds had healed, and the plaster was continued until about the middle of July. The notes in detail are unimportant; but to-day, on examination, the child is found to be perfectly well, fairly well nourished, and improving without any interruption. Is able to stand and walk a little; has had no plaster or splint on since the middle of July; wounds are tightly healed; functions of the joint very nearly perfect, A. G. E. being 180° and flexion up to an acute angle, rotation about one-half normal. No reflex spasm; little or no laxity about the joint; abduction and adduction good. The comparative measurements were: R. A., 11; R. U., 12½; R. T., 3 inches down, 6¾; R. K., 6.; R. C., 5. L. A., 11; L. U. 12½; L. T., 3 inches down, 6½; L. K., 6.; L. C., 4¾.

Case II.—Sarah A——, aged ten months, the father Carlo A——, of Baxter Street, rear house, second floor, presented at my clinic on May 7th with an immense abscess over the left hip, with an anterior curvature of the spine that caused me to strongly suspect disease of the vertebræ. The abscess extended over past the vulva, posteriorly, past the median line. The disease was of recent date, the child suffering very much, thigh held flexed and excessively painful. A free incision was made, front and back, a large quantity of pus evacuated, and, on thrusting the finger into the sac the head of the femur was lying very nearly loose. The bistoury was inserted and a small cartilaginous attachment cut away. The acetabulum was curetted, sac also curetted, thoroughly cleansed with corrosive sublimate, packed, and full dressing applied, plaster of Paris from foot to axilla. Dose of paregoric administered, child sent home.

On the 13th the improvement was very marked. Discharge very slight. Drainage-tubes inserted; re dressed with plaster. Temperature at this date was 100.2° F.

May 7th.—Child doing well.

May 11th.—Wound granulating. Tubes removed. Child gaining flesh. A more snugly fitting plaster-of-Paris bandage applied.

May 14th.—An abscess had formed on the inner side of the thigh, which was opened and drained by iodoformized gauze tent.

[1] Read before the Practitioners' Society of New York, October 7, 1892.

September 7th.—The plaster was finally removed about the middle of July, all the wounds having long since healed, and a snug roller bandage applied. Saw the case to day for the first time since the plaster was removed. Child rather fat, well nourished. The movements at the hip very nearly perfect. A. G. E. 175°; A. G. F. about 45°. Abduction nearly perfect. Rotation over two-thirds normal arc. Adduction good. Hip seems firm and child can walk on it.

R. A., 12; R. U., 14; R. T., 3 inches down, 8¼; R. K., 7; R. C., 6¼. L. A., 12; L. U., 14; L. T., 3 inches down, 8¼; L. K., 7; L. C., 5⅜.

It will be seen that in the first case the bony structures were not involved. It was really a periarticular abscess, and although deformity had arisen and the probabilities were that the process would have extended rapidly to the joints, an excellent recovery has been obtained by simply free incision, drainage, and immobilization.

In the second case the head of the bone was found loose in the cavity and was removed, and yet, under the same treatment, a perfect result has been obtained. It may be further noted that these cases were not in hospital, that they required very little attention at home; in fact, I think that they were visited only once or twice during the whole course of the disease. They were brought back and forth to my clinic, the dressings attended to at the clinic, and in every instance the plaster-of-Paris was renewed, so that the parts were kept in good position all the while. The treatment, therefore, which I insist upon, and which I think is justified by the two cases here reported, is early incision, thorough evacuation of all abscess cavities, correction of deformity and shortening at once, free drainage, and immobilization continued throughout the entire period of repair.

I feel that it is unnecessary to take up your time with any lengthy remarks on the use of plaster-of-Paris, or I should like to insist on its more frequent employment in surgical dressings, especially where joints are involved and where it is important to secure absolute rest to the parts. I know that many surgeons object to plaster, because it is difficult to properly apply, and because they fear excoriations and discomfort. These objections can easily be overcome, and I am free to say that no immobilizing apparatus with which I am familiar has given me anything like the satisfaction that I have obtained from the plaster-of-Paris

---

Symphyseotomy.—Charpentier declares that, thanks to antiseptics, symphyseotomy is an operation which gives excellent results when the pelvis is contracted to a conjugate between two and one-half inches and three and three-tenth inches. It almost assuredly allows the operator to save both mother and child. It spares the obstetrician the cruel necessity of sacrificing a live child, or of waiting for its slow death when he cannot make up his mind to perform cephalotripsy as long as the sounds of the fœtal heart persist. This delay seriously affects the mother. Symphyseotomy has a very limited scope, clearly defined. It stands between premature delivery and Cæsarean section, and associated to the first of these obstetrical interventions it allows the otherwise forfeited lives of the children to be saved. Like Cæsarean section, embryotomy should become an exceptional operation, and it is especially embryotomy that the operation of symphyseotomy should render a thing of the past in obstetric surgery.—*British Medical Journal.*

Acute Yellow Atrophy and Syphilis.—Dr. Engel Reimers reports three cases tending to support the view that acute yellow atrophy of the liver is a result of the syphilitic poison. In these cases the first symptoms appeared about seven months after the primary sore. Therapeutic measures were without avail, but the reporter had the satisfaction of seeing his diagnosis confirmed at the autopsy in each instance.

PROCTO-PLASTIC OPERATION FOR CURE OF CICATRICIAL STENOSIS OF THE ANUS.[1]

By L. J. KROUSE, M.D.,

CINCINNATI, O.

HARRY H——, aged about four, living in an adjoining city, was brought to the surgical clinic of the Medical College of Ohio, in August of 1890, with the following history: About two years ago (in December of 1888) he was suffering from retention of urine, and a hot water sitz-bath was ordered for him by the attending physician, who placed the patient in the bath and held him there for at least half an hour, notwithstanding his protestations that the water was too hot. At the expiration of that time he was removed from the bath, and it was then noticed that the perineum and lower part of the bowels as well as the buttocks on each side were reddened and an immense bulla, the size of a child's head, soon made its appearance, covering that area.

After a few days this bleb ruptured and the underlying parts were then found to be covered by a grayish black mass, which soon sloughed off, leaving an ulcerated surface that required over two years and a half to granulate and cicatrize.

He was brought to the dispensary on account of difficulty in defecation and of constantly soiling his clothing. He presented, on examination, a healthy general appearance, giving no idea of the pain and suffering that he had undergone. He had entirely recovered from the emaciation that had been present for a long time.

Looking at the region involved, it was found that the lower outlet of the pelvis was one mass of cicatricial tissue, limited anteriorly by the scrotum, extending posteriorly nearly to the upper part of the sacrum and encroaching on each side on the buttocks and thighs. Its outline resembled very much that of the conventional representation of a heart, with the apex pointing forward.

The scar tissue was pale in color and glossy in appearance, showing that the parts had been healed for some time. It was not of uniform thickness, but seemed to be much thicker behind the anus and on each side of it than it was in front.

Near the anterior portion of the cicatrix was an oblong opening, compressed from side to side, with its greatest diameter from before backward, which opening led in a funnel shape to the anus. This was filled up with fecal matter.

On attempting to introduce the little finger into the anus, it was found that this orifice was so small that the tip of the finger could not enter, and that the orifice was patulous, being held open by the dense cicatricial tissue of which its walls were formed.

In order to determine more accurately the size of the opening as well as the length of the stenosis, use was made of Otis's urethrometer, which registered as it entered the stricture 25 of the French scale, and after passing one-half inch into the bowels the instrument could be dilated to its full size, showing that the scricture was of limited extent.

Before resorting to operative measures, attempts were made to cause an absorption of some of the cicatricial tissue surrounding the anus by massage and the daily introduction of bougies. At first we were rewarded by slight improvement, but this did not continue long; irritation and ulceration followed the use of the bougies, and it was soon apparent that, as in resilient stricture of the urethra, nothing could be done but to thoroughly split the stricture with the knife. The boy was therefore sent to the hospital, and on December 6, 1890, with the assistance of Drs. Marcus and Carroll, I performed a modified Diffenbach's operation, which consisted in splitting the contracted orifice both anteriorly and posteriorly. The anterior incision extended through the cicatrix into

[1] Read before the Cincinnati Academy of Medicine, January 25, 1892.

the healthy submucous tissue; the posterior cut was carried backward into the dense cicatrix to the extent of about half an inch. A tongue-shaped flap of skin, an inch and a half in length by three-quarters of an inch in width, was then dissected from the scrotum and perineum and slid back into the anterior incision and attached to it and to the gut by numerous silk sutures. Into the posterior cut another flap of skin was sewed, but this flap did not come from the immediate vicinity, but was dissected from the healthy tissue of the left buttock outside of the scar, and it had to be twisted before being sutured to the cut.

The patient rallied nicely from the operation. The bowels did not move for several days. There was no rise of temperature.

The stitches were removed on the eighth day, and it was then found that the anterior flap had united nicely, while the posterior one had died; no doubt its death was due to the poor blood-supply of the dense cicatricial tissue to which it had been sewed.

There were no unfavorable sequelæ in the progress of the case, except that on several occasions it appeared very much as if the stitches would be torn loose on account of the large fecal accumulation which pressed upon the parts and protruded from the anus. This accumulation was removed artificially by means of the sharp spoon-like handle of the scalpel.

The dilatation of the pouch directly above the sphincter muscles was so great that it took considerable time and a good deal of patience to thoroughly remove the fecal matter.

The patient was discharged at the end of the third week with an anus that readily admitted the index-finger of the right hand. A bougie was used regularly for some time after the patient left the hospital.

It seemed remarkable what improvement had taken place after an operation of so little magnitude. Here we had a patient who, before the operation, was always soiling his clothing; he was a nuisance not only to himself but also to his companions; and he was frequently sent home from Sunday-school by his teacher.

His incontinence came not from a weakness of the anus but was due to an over-accumulation of fæces in the rectum pressing upon a contracted and patulous anus. The lower bowel was always full, and it was only by means of oil and enemata that a movement could be obtained, and even with the assistance of these remedial agents the patient was compelled to strain so much that by the time his bowels had moved he was completely exhausted.

At present we have an entirely different picture, the boy does not complain of anything, he enjoys the best of health; he goes to school and is not troubled with involuntary discharges of fæces. He has a daily movement of the bowels, and, as his mother informs me, they are normal in size as well as in form. The sensation of these parts has returned, and the patient always notifies his mother whenever he wishes to go out. He never soils his clothing, not even, as his mother informs me, when his bowels are loose.

The question naturally arises, What gives the boy such control over his bowels? The external sphincter muscle is destroyed, and if it were not the muscle would be so thoroughly incorporated with the cicatrix that its function would be completely annulled. We must look elsewhere for an explanation. The nerves of the parts have regained a good deal of their lost sensibility, and this may account partly for it, for as soon as the fecal mass reaches the lower portion of the rectum the desire for an evacuation comes on and the patient then notifies his mother of the fact.

But the more plausible explanation is the one based on the mechanism of the parts. If we look at the anus, we find an opening longitudinal in shape, whose lateral walls are parallel, being composed entirely of dense fibrous tissue.

These walls are not kept asunder as they were before the operation by the stiff unyielding anterior wall, but are allowed to approximate by the thin delicate skin which is interposed between them.

When the bowels move the opening of the anus takes more of a triangular shape, with the apex backward, resembling very much that of the rima glottidis during deep inspiration, while in the quiescent state of the bowels, the walls of the anus run parallel to each other like those of the true vocal cords during phonation. To both of these causes do I ascribe the good retentive power of the anus.

THE PERMANENT WARM BATH EMPLOYED IN ARTICULAR INFLAMMATION.[1]

By A. ROSE, M.D.,

NEW YORK.

In December, 1889, I read before this Society a paper on the employment of the permanent warm bath in cases of erysipelas of the extremities. I wished to show the powerful effect of the warm bath on this infectious inflammation, to show how the temperature was thereby promptly reduced and how the whole course of the disease at once changed for the better.

I attempted to explain this fact by presuming that the permanent bath, which in fact was only a few degrees less than blood-heat, reduced the temperature; that the parts, after being for a while immersed, became swollen, and lost their faculty of absorbing pyrogenic matter on account of the connective tissue having become too tense and the lymphatics being obstructed. Thus erysipelatory infection by way of lymphatics would be impossible, the focus of infection being excluded, while the pyrogenic matter was carried, by way of increased blood-circulation, out of the system.

To-day I wish to communicate an observation upon the remarkable effect of the warm bath on arthritis and its influence on innervation, circulation, and tissue metamorphosis; also its efficacy in relieving pain and aiding absorption.

Considering the permanent bath as a therapeutic measure, we find fixed laws to govern its employment are yet to be determined, and much which is known is to be complemented in several directions. Some facts, although founded upon experience, should have a scientific, a physiological basis. Of hydrotherapeutics in general it may be said that many rational facts found by scientific research would be retained if numerous as yet isolated truths of experience would have been appreciated according to their value, instead of being lost to memory and to practice. "Not the remedies, but rather the methods of treatment, will be the feature in future," says Ziemssen. Hydrotherapeutics will become a more and more scientific method of treatment, a method founded upon physiology.

Delia G——, the patient whom I present to the Society, is of Ireland, twenty-four years of age, always well before, and of remarkably strong muscular development; was taken ill toward the end of September, 1891, with rheumatism of the left elbow joint; there were unusually severe symptoms of inflammation, especially violent pains. Several antirheumatics gave little or no relief, even antipyrin did not ease the pain or procure sleep for the night. Of all the remedies employed it was only the plaster-of-Paris bandage which gave some satisfaction. I left this bandage on for a fortnight, and a second time for ten days on the arm, and removed it when I had reason to suppose that the symptoms of inflammation, viz., swelling, pain, and increased temperature, had subsided. This proved to be the case whenever I removed the plaster-of-Paris.

Soon after I had removed the first bandage symptoms of inflammation reappeared; after removal of the second, stiffness of the joint remained. It was only while the

[1] Read before the German Medical Society, New York, May 2, 1892.

patient was under the influence of chloroform that I was able to bend and to stretch the arm. While I made these forced flexions and extensions, frictions, the symptom of synovitis fibrinosa could plainly be felt. The forced flexion and extension under the influence of chloroform gave no permanent result. On the contrary, the exudation in the synovial cavity increased, and mobility was reduced to a minimum. The perisynovial soft parts became infiltrated, and added to the increase of immobility.

At this time patient could and would not remain with the family who had hired her to do general housework, and on November 30, 1891, she became an inmate of St. Francis' Hospital, of this city.

One of the physicians of this institution told me that according to his opinion the prognosis in regard to the usefulness of the arm of my patient appeared doubtful. The treatment, he informed me, consisted in forcing the joint, which could be brought to a right angle with difficulty, by means of graduated bandages into an acute angle. The patient said that during her stay in the hospital she took no medicine of any kind.

On December 12, 1891, she left the hospital. I now found the arm in the same condition as before she entered the hospital. To bring the joint from an obtuse to a right angle gave the patient considerable pain; and to go further in the way of flexion I regarded as too risky.

On December 15, 1891, I had the arm submerged in a warm bath, the bathing-tub consisting of an oval-shaped wash-boiler. I ordered some water taken out hourly and hot water added to keep the temperature as high as would be consistent with the patient's comfort. For the night moist compresses covered with flannel bandages were substituted. No medicine while the arm was treated by permanent submersion.

The patient had followed my orders only too conscientiously. She had taken the water so hot that it scalded hand and arm, the epidermis became raised in the shape of numerous blisters. I did not place much stress on this accident, because, according to my experience, the warm bath simply continued would be the remedy for the effects of the too hot bath. Such proved to be the case. No pain or ill consequence of any kind followed.

The effect of the permanent bath was highly gratifying. All pain the patient had been complaining of ceased at once. From day to day I could make more extensive flexions and extensions of the arm without causing violent pain to the patient. The comparatively slight pain which I caused now while making passive motions disappeared very soon when the arm was submerged again.

On the third day the patient herself could bring the elbow-joint to a right angle, the following day she could do this without causing any pain. On the fifth day she brought the joint to an acute angle, and on the tenth day flexion and extension were normal.

Since that date (December 26, 1891) patient has been attending to her housework, she is able to do washing and ironing for the household. Unfortunately she is still exposed to the danger of rheumatic invasion, and from time to time new rheumatic attacks in the elbow-joint supervened. I wish to repeat that during the time of permanent submersion, that is from December 15th to December 26th, patient took no medicine whatsoever. Since then, whenever new rheumatic inflammation has set in, the case has been benefited by salipyrin. However, when pain and other symptoms of new inflammation appeared, I ordered the arm to be placed in the warm bath for one or two hours at night, and the result was invariably that this relieved the pain.

I have to confess that, as you will perceive, the arm even to-day cannot be flexed quite as far as the sound one, also that there exists a minimal swelling at the elbow-joint; but I am convinced that if my patient would desist from work and could for days employ the warm bath, and, above all, be removed from all causes of new rheumatic infection, these comparatively slight remnants of rheumatic inflammation would disappear completely.

While I was treating this case I was not aware that the method employed by me had been practised by others, and even after I have now looked over the literature, as far as I had access to it, I find that very little has been published on the subject. Dr. A. Jacobi, to whom I first communicated my observation, called my attentention to a similar method of treatment which is in use at Leuk. What I found described of the Leuk method is the following:

"Leuk, in the canton of Wallis, 1,415 metres above the sea, situated in a ravine with grand Alpine scenery. The water of the springs is of 41.5° and 51° C. (107° to 123° F.) temperature, and contains sulphate of lime, sulphate of magnesia, and other salts, besides a small trace of carbonic acid. As a bath it is to be classified as an indifferent therme—the sulphate of lime is neither absorbed nor can it irritate the skin—on account of its being contained in the water in too small quantity.

"The average course of treatment is calculated to last twenty-five days, during which time either every second day or every day the patients bathe once or twice during the day. The duration of the bath is in the beginning one-half hour, and is increased gradually to five and eight hours, divided between forenoon and afternoon; after eight to twelve days of gradual increase there is gradual reduction of the duration of the bath until the initial bathing-time has been reached. Ladies and gentlemen bathe at the same time in one common basin, the size of which is calculated for twenty persons. The bathers pass the time in conversation, reading, and playing dominoes on floating little boards. At noon the basins are partly and at night they are completely, emptied and replenished. During the night the temperature of the water sinks to about 35° C. (95° F.). The diseases treated thus are gouty and rheumatic exudations, chronic exanthemata, psoriasis, eczema, prurigo."

Hueter recommends in polyarthritis synovialis acuta (rheumatismus articulorum acutus), after the acute stage has passed, and also in polypanarthritis (arthritis deformans), therapeutics which aid absorption and excite circulation, and praised, as the best means to this end, permanent warm baths, either for arm or leg, in tubs of proper size and shape, or general baths, as the case may require. He states that this therapeutic measure in polyarthritis synovialis chronica, as well as in polypanarthritis, had not been surpassed by any other method of treatment. He says: "In regard to polypanarthritis it is well known that no remedy is perfect, not even the permanent bath, but the permanent bath gives more satisfaction than all the other remedies."

Riess [1] recommends permanent warm baths in articular and muscular rheumatism; he spreads a bathing-sheet, like a hammock, above the bath-tub in such a manner that the patient may rest on this sheet in the water. The head rests on a rubber ring.

It is a well-known fact that a warm bath of long duration is mostly well tolerated. To emphasize this fact I shall give an extract of a communication from Dr. Baelz [2] on the permanent thermal baths of the Japanese: "The Japanese bathe in indifferent or slightly salty, thermes of 42° to 48° C. temperature, ten to fifteen times daily. Of special interest is a rudimentary bathing establishment situated in the mountainous region of Dzooshin, named Kawanaka. It is an Indian therme of 36.2° C. The patients remain in the water not only whole days, but for weeks at a stretch. They only leave the water to attend to calls of nature, or occasionally to take a little exercise. The body is placed in a half-recumbent or otherwise comfortable position, the occiput and neck rest on the margin of the wooden basin, in which a number of patients at the same time are gathered together. To prevent the rising to the surface during sleep the bathers place a more or less heavy

[1] Berl. klin. Woch., 1887, 29. [2] Ibid., 1884, 48.

stone across their groins. The proprietor of the bathing establishment, a man seventy years of age, remains during nearly the whole winter in the water—without garments and without stove he feels comfortable and warm, while outside snow covers the ground for four or five months in succession. His functions and his general condition are normal."

To comprehend the therapeutical value of the permanent warm bath we shall have to study the elementary effect of the warm bath.

While by the cold bath the muscles and the capillaries of the skin, and of those tissues to which the effect of the cold extends, are made to contract—a contraction which, after the irritation produced by cold has ceased, is followed by dilatation, the local anæmia is changed into hyperæmia—the mechanical proceeding under the topical effect of warmth runs in the opposite direction; the tissues relax, the capillaries become dilated and filled; in the beginning, if the effect is a strong one and of long duration, even passive stasis may be the result. After cessation of the thermal irritation contraction of the vessels takes place and renewed quickening of the circulation. The experience which we can have by bathing our extremities, and observation of the circulation in the web-membrane of the frog, confirm both equally well the difference in these two processes: the effect of cold is temporary contraction followed by dilatation; of warmth, temporary dilatation followed by contraction.

If a limb is left in warm water for some length of time the soft parts become swollen, quite considerable increase of volume takes place, and after removal from the bath the skin of the submerged limb is warmer, often quite red, which discoloration disappears only after a few days.

Winternitz made experiments in the institution for experimental pathology of Professor Stricker, of Vienna, in measuring the increase of volume of the limbs subjected to baths of different temperatures. Employing for this purpose an ingenious contrivance he was enabled to measure, on the arm suspended in water in the apparatus, increase of volume, which occurred simultaneously with the pulse-beat, and was caused by the large amount of blood driven into the arm with each systole of the heart, also changes of volume which corresponded with the larger amount of blood passing out during each interval between two systoles. He could establish the fact that the change of volume of the arm suspended in water of 8° C. could well be distinguished from the one obtained when the arm was suspended in 38° or 40° C. In the former experiment each heart systole presses only a relatively small amount of blood into the arm. The reason of this can only be—the strength of the heart's action not having materially changed during the experiment—that there is a greater power of resistance of the blood-vessels (which have been contracted by the effect of cold); this power of resistance opposes the entering of the blood-wave to a certain extent.

The by far greater deviations of volume of the submerged arm can only be plausibly explained by assuming that the long lasting effect of the warm bath had caused dilatation and relaxation of the vessels. With each systole of the heart more blood is driven into the arm, on account of the reduced resistance of the vascular walls, the lumen of the vessels thus enlarging considerably. This explains the enlarged volume.

Winternitz thus demonstrated *ad oculos* by his experiments that when some part of the body is submerged in warm water a considerably increased amount of blood passes into it with each systole, and a correspondingly large amount flows back through the veins during the intervals.

Indifferent baths, however, according to Jacob,[1] likewise affect to a certain degree the circulation. As a rule the skin is from 5° to 10° C. cooler than the axilla. The normal indifferent temperature of the bath, which is 35° to 36° C., increases the temperature of the skin to almost the same degree of temperature of the internal organs, the latter sinking generally to 0.5° to 1° C., the outside temperature rising to such extent that there is often found a difference of only 0.5° C. in favor of internal temperature. This sinking of the internal and rising of external temperature means acceleration of blood circulation, mostly accompanied by slight reduction of frequency of pulse, and is followed necessarily by relaxation of muscles, stimulation of sensory nerves, and calming of nerves of warmth and pain.

[1] Virchow's Archiv, Bd. xcvi.

The warm bath, while it surrounds the surface of the body, or part of the body, with an equally tempered medium, does away with fluctuation as to space and time of the loss of heat, and thus acts soothing. This is of especial advantage for therapeutical purposes. It is probable that a law exists according to which soaking of the peripheric ends of the nerves reduces, and drying increases their excitability. At least Heyman[1] thinks it possible that the calming effect of the warm baths is superinduced by suppression of perspiration, and thus retention of moisture, which proceeding takes place during the bath, and which causes, in the first instance, soaking of Krause's end clubs and Meissner's sensory bodies; in second instance, cessation of moleculary movements in the extremities of the nerves, and thereby general calming of the nervous system.

In the paper mentioned above I cited the example of Napoleon, who while at St. Helena, and while the monotony of his life was only interrupted by the pains he suffered from his cancerous disease, found relief when he remained for hours, or even whole days, in the warm bath.

It is to be supposed that the permanent warm bath will prove serviceable in sciatica.

Numerous physiological facts are known which support the theory that withdrawal of water excites the nerves, while gradual taking up of water (assimilation) reduces the irritability of nerves. On this theory is based the hypodermic injection of water to produce local anæsthesia.

The thermic irritation of nerves, while it lessens the sensation of pain, excites at the same time, by way of reflex action, especially in the muscle, an increased change of substance (Stoffwechsel). To relieve pain in the muscles caused by fatigue, there is no better means than a warm bath. Even comparatively high degrees of temperature have a refreshing effect. The fatigue or exhaustion of muscles is caused by more than normal accumulation of the products of their function. To oxydize and eliminate these products a certain amount of change of matter (Stoffwechsel) is required, which charge the fatigued muscular fibre is unable to perform. The specific effect of the warm bath is to afford immediate facility for oxidation. Without the warm bath this relief would only be obtainable after bodily rest of hours or days. To illustrate this I refer once more to the striking example of Napoleon. In the evening after a battle, instead of seeking rest and sleep in bed, he would take a warm bath, to enable him to resume the march during the night and fight a second battle the following day. On the morning of June 21, 1815, when he arrived, coming directly from the battle-field of Waterloo, in the Elisée, and dismounted from his carriage, he had to lean heavily on the arm of Caulaincourt, and he asked for a warm bath. Six days he had been on horseback nearly all the time. While he was in the bath Davout came twice to urge him to come to the assembled ministers. There was no time given for long rest, the warm bath alone stimulated him to renewed activity.

The changes of the physical and chemical condition of tissues, the augmentation of the organic functions, the acceleration of the blood-circulation, the dilatation of the vessels, all this depends on specific action of the warm bath on innervation. The effect produced by the

[1] Virchow's Archiv, Bd. l.

thermal irritation of the extremities of the nerves is manifested primarily at the point of contact and along the centripetal tracts originating from the point of contact, and secondarily, in the central organ itself, as also conveyed from there by the centrifugal motor tracts.

This irritation causes also change of innervation at the point of contact itself, as well as in all the motor and trophic fibres which are related to such point of contact as long as they are by conveyance or reflex action connected with the region of irritation. It is to be noted, however, that the effect on the motor fibres is not exclusively one of reflex action, as far as the point of application (of thermal irritation) is provided with a multiple net-work of ganglia; and it suggests itself to the mind that these ganglia may act as so many peripheric centres having a direct influence on such formations as are provided with these ganglia, an influence independent from brain or spinal column.

The thermal effect may not only increase innervation, that is, direct'y excite, but may also produce the opposite effect, that is, reduce irritation. This depends on the amount of strength or duration of one and the same agent, in some cases by over-fatigue or by excitation of so-called checking nerves (Hemmungsnerven).

Cold as well as warmth may produce temporary retardation, but also an accelerating effect on the process of Stoffwechsel.

The degree of primary Stoffwechsel caused by reduction of heat—during lasting reduction of heat the Stoffwechsel becomes tardy—depends on the degree of the reflex excitement of the muscular tonus or the muscular contraction thus excited. The more potent the thermal excitation of nerves, the more considerable will be the reflecting acceleration of the process of Stoffwechsel.

If I wished to give an exhaustive treatise, I would have to enter elaborately into the description of the effect of the warm baths on the Stoffwechsel; I should have to speak on their effect of increasing the formation of urea, the variation of oxidation under various degrees of temperature of the baths; I should report the result of the different experiments on the Stoffwechsel in connection with warm baths, but I do not wish to extend my paper thus far. I will only mention that, notwithstanding clinical experiences we are in need of experiments on this subject. The results of the different experiments thus far made and published are treated in Leichtenstern's book on Balneotherapy, which forms part of Ziemssen's work on general therapy.

We shall remember that the irritation of the peripheral nerves caused by warm baths have, as illustrated in the case cited above, a gratifying effect on the accumulated pathological products by increasing the amount of blood on the surface and relieving the overcharged parts below by accelerating the general circulation.

Reflexes in Hip-disease.—Dr. Brackett says that in cases of coxitis the condition of the patellar reflex depends on the same general causes as the muscular spasm. When muscular spasm is absent the reflexes are not altered, but if the joint is irritable the reflexes will be increased on the diseased side. "The presence of subjective symptoms does not apparently affect the phenomenon. The value of this is twofold: it becomes an indication of the irritability of the joint in the absence of subjective symptoms in the same way as does the involuntary muscular spasm, and also of diagnostic value in the early stages in the absence of other indications. In this it can be used as one of the evidences in distinguishing between early hip and low lumbar caries. for a marked difference is shown in the case of spinal caries in this matter of reflexes, as these show an almost constant uniformity, and are not only equal but much less likely to be exaggerated even with the presence of other disease." In cases of long standing, in which atrophy is marked, this sign is of less value.

Progress of Medical Science.

Red Bilberry (*Vaccinium vitis idæa*) **in Articular Rheumatism.**—The red bilberry is a popular remedy in Siberia for rheumatism. Smirnoff (*Rép. de Pharm.*, July 10, 1892) reports excellent results from decoctions of the whole plant, in doses of thirty to sixty grammes to a pint of water. This drink should be taken for three months steadily. It is especially efficacious where salicylates, iodides, and antipyrin fails.

Nervous Disease During Græco-Roman Antiquity.—Though neuropathology as to-day understood was unknown to the Græco-Roman period of history, there existed a certain acquaintance with nervous disease that two Frenchmen, Michel de Tornery and Papillon, have put into book form (1892), with the foregoing title. There are in ancient writings magistral descriptions of epilepsy, hysteria, and mania, characterized by shrewd powers of clinical observation. Hippocrates, for example, states that. after injuries to the skull, paralysis is on the right side if traumatism affected the left, and *vice versa*. Celsus describes the difference between hysterical and epileptic seizures, and states that hysteria also exists in the male. Even then, as to-day, the most bizarre remedies were in vogue. The ancients used testicles of animals as remedies for nervous disease, content, however, to have them absorbed by the digestive tract. Yet the idea is the same in essence as that embodied in treatment by means of the late famous elixir.

Hygiene of Childhood.—While recognizing the advantages of the Parisian house, Grellety, in a recent monograph, deplores the lack of space in children's rooms. In the finest, the best rooms are reserved for state apartments and those overlooking court-yards are given to children. The air is not pure; and even when infants pass part of the day in public parks, they fail to get sufficient oxygen during the twenty-four hours. Less parsimony in the matter of light and air would be rare good fortune for the little ones.

Height and Health.—In the *Annales d'Hygiène*, April, 1892, G. Carlier, an army surgeon, gives some interesting statistics concerning height, which is largely an affair of nationality. Americans are tall, according to the author, because of creature comforts and material prosperity that prevail in their country Possibly a factor of equal importance is that the majority are descendants of Germanic tribes, notably the Anglo-Saxons and Teutons. The height of conscripted French soldiers is arranged in the paper according to occupation. The student class and farmers are tallest; mechanics, printers, masons, servants, etc., come next; and weavers and shepherds shortest. In prosperous regions height is greater than in poorer provinces. Among disabilities and negations for admission to the French army are insufficient height, myopia, goître, epilepsy, and tuberculosis

Vesical Tumors in Children.—Phocas, of Lille, reports one case of his own, in a child six and a half years old, who was operated upon for vesical tumor, of which a portion was removed. Transient benefit only resulted, the neoplasm growing again and death following speedily. To this the author adds the thirty others that literature furnishes. Malignant growths in the bladder are more frequent than benign; troubles of micturition are common in both sexes; in girls diagnosis is easy, as the vesical tumor dilates the urethra and appears at the orifice; in boys, the bladder seems to be dilated, but on introducing the catheter no urine is found; diagnosis is completed by rectal exploration joined to abdominal palpation. Cures have only been obtained in benign tumors. In event of malignant growth, death comes rapidly. As this is the rule, is it not better to refrain from operating?

Clinical Department.

THE TOXIC EFFECTS OF ANTIFEBRIN COMPLICATED WITH ALCOHOLISM, ILLUSTRATED BY A CASE.

By W. F. GRIER, M.D.,

'MASTER IN SURGERY (GLASGOW UNIVERSITY),

NEW YORK.

An urgent call recently took me to a lady supposed to be dying. On arrival I found the patient, aged forty-five, seated bolt upright in bed, propped by pillows. With something more of a curious and anxious than alarmed expression she was intently gazing on the reflection of her features in a hand-mirror.

There was no marked dyspnœa, but the face displayed a ghastly cyanosed appearance, the lips being purple, while the superficial capillaries of the face were mapped out, particularly along the margins on the alæ nasi and over the cheek-bones. The general aspect of the face was of a dusky ashen-blue-gray appearance, so also with the hands and feet, the hue of the nails served to heighten the livid appearance. Stigmata appeared on the chest and various parts of the body.

Examination of the case disclosed the fact that the patient was a dypsomaniac, and had just ceased a day or so before from a period of indulgence in brandy, whiskey, and port wine alternately. As is often the case in confirmed alcoholics, she displayed no evidence of intoxication in her speech, which during my first visit was evidently being controlled and restrained. Ample evidence, however, was forthcoming, that the dregs of a drinking bout circulated in the system, and complicated the case. She was exceedingly restless, and on my second visit opened up a fire of artillery, first against her husband, next against her mother, and lastly against me.

It was elicited that in addition to the stimulants taken for indulgence, the patient had been almost incessantly drugging herself with various remedies, among which may be mentioned, blue pill, Hunyadi Janos water, citrate of magnesia, sweet spirit of nitre, sal volatile, and lastly antifebrin, of which she had taken ten grains at 8 P.M., and the same quantity at 11 P.M., 2 A.M., and 7 P.M., in all forty grains within eleven hours.

The respiration was 19, heart action rapid, but while I could not make out any murmur I was not satisfied that the heart-sounds were pure over the aortic area and down the sternum to the ensiform cartilage. I was much impressed by the character of the pulse at the right wrist, which numbered 104, as it reminded me of pulses I have observed similar in character in aortic aneurisms. This caused me to examine the pulse at left wrist, which I found from four to five beats per second quicker (counted over several minutes) and much fuller, of lower tension, and of easier compressibility. At the manubrium sterni a distinct prominence was noticeable, which the patient, seeing me observe, palpate, and percuss, remarked was "a periostitis!" I could not make out any definite signs, such as fremitus, bruit, etc., indicative of aneurism, yet it is only right to record the possibility of a fusiform aneurism, particularly as the age and habits of the patient, together with the suspicious facts noted, favored such an idea.

The tongue on being protruded was seen to be so large that one wondered how the mouth could contain it. It was heavily coated with a yellowish white fur, the breath being exceedingly offensive.

Treatment.—Upon general principles I determined to treat the case as one of acute alcoholism, therefore gave her ten grains of calomel at the outset. After the lapse of one hour I commenced the administration of small doses of nitro-glycerine, one-half drop of a one per cent. solution being given every hour, and the regimen restricted to small quantities of peptonized milk and meat-juice.

In the course of twenty-four hours the cyanosed condition was materially improved, the tongue lessened in bulk and cleaner. The restlessness diminished and the pulse fell to 80. Not wishing to push the effect of the nitro-glycerine any further, I now gave her tincture of digitalis in ten-minim doses as a heart tonic and non-intoxicating stimulant. On the third day the cyanosis had disappeared and the patient was in a more normal condition, while on the fifth day she was completely restored to her usual health.

No other drug was administered, except a sedative of twenty grains of chloral and thirty grains of ammonium bromide to secure sleep at night, and a saline purgative on the second day to flush out the intestines after the administration of the large dose of calomel given in the first instance.

The patient has gone away to the country, but I hope on a future occasion to more minutely examine the circulatory system for aneurism.

Remarks.—The salient and alarming features of the case for which I was called in were undoubtedly due to poisoning by antifebrin administered by the patient herself to counteract the evil effects of her drinking, and it illustrates the great danger of a "little knowledge" of drugs and their effects.

Much of this popular knowledge is due to the practice of some well-meaning yet unwise practitioners, who discuss with their patients the nature of the remedies which they employ and their therapeutic action. The result, it appears to me, of this prevalent fashion is: 1, Greatly to lessen the reliant faith which patients should have in their physicians; 2, said patients, becoming at last convinced they know all that is necessary concerning their diseases and treatment, drug themselves, albeit to their own detriment; and 3, not until some such alarming set of symptoms as those here recorded have arisen do they call in a physician again, which to some degree must account for the hard struggle which the rank and file of practitioners in New York experience in order to make "both ends meet."

The glib and voluminous discourses of this patient on drugs, and their effects upon the normal and diseased system, almost appalled me, and but for the presence of her mother I should have been dismissed from attendance on the case, because, forsooth, I refused to inform her as to the remedies employed—this being, she said, the only time her intelligence had been so insulted! Every physician, hitherto, had told her the details of his treatment, etc.

Before closing this paper I am induced, from having noticed several contributions on the treatment of alcoholism in the MEDICAL RECORD, to draw attention to the beneficial effects, in such cases, of large doses of calomel (which is easily administered dry on the back of the tongue, even in a delirious case). It acts as a sedative on the stomach, powerfully increases the secretion of bile from the liver, removes depressing sulphur gases and toxic compounds, generated there by excessive abuse of alcohol, and, by their removal, calms the much-irritated nervous centres.

The general treatment of such cases, without any doubt, should involve the immediate and total cutting off of stimulants, the supplying of bland, unstimulating, easily digested food, and the administration of hypnotics of a reliable and harmless nature, such as chloral combined with ammonium bromide.

425 LEXINGTON AVENUE, September 19, 1892.

Wooden Spatulas.—The facility with which infectious disorders of the mouth and throat may, in spite of careful cleansing, be transmitted to the well by the use of the same tongue-spatula for many patients, has led to the manufacture of a small, flat, wooden spatula, which, for a single examination, answers its purpose as well as more costly implements, and can be burnt after use.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS
WM. WOOD & CO., 43, 45 & 47 East Tenth Street

New York, October 29, 1892.

TUBERCULOSIS IN THE WHITE HOUSE.

THE sad death of Mrs. Harrison, after a lingering illness, has aroused a natural and widespread sympathy for the afflicted President. To physicians who have followed the story of the sickness and of President Harrison's devotion some thoughts of the danger to which he himself has been subjected will arise. Mrs. Harrison died of pulmonary tuberculosis, after an illness of less than a year. The deceased was in her fiftieth year, and might, perhaps, have been expected to be beyond the ordinary dangers from phthisis, though there was said to be a hereditary history of the disease. A year ago Mrs. Harrison had a severe attack of the grip; early last spring she had pneumonia, which was probably tubercular, and was followed by a hemorrhage. The disease seems to have steadily progressed since that time.

In the light of modern knowledge, tuberculosis is an infectious malady, and one which conveys some danger to those in close attendance, unless proper care is taken. The disease also may infect a room or house and render thorough antisepsis most important for those who dwell there. It is to be hoped that the proper precautions will not be neglected in the present case.

THE HAIR AND SURGICAL OPERATIONS.

THE preparations for a modern surgical operation have gradually developed themselves into a ceremonious observance that awakens interest and awe in the mind of the layman, and even of the plain non-surgical doctor. The boiling, the scrubbing, the putting on of uncouth garments, the patient attention to manicuring processes, are details that are watched by the devout with feelings of religious approbation. The practice of dyeing the upper extremities a dark brown with permanganate of potash and then decolorizing is at once an object-lesson in chemistry, chromatics, and laundry-work. It does not seem as though much more could be done to elaborate or adorn this sacerdotal stage of the modern surgical operation. Yet Dr. Oscar J. Prince intimates (in the *North American Practitioner*) that something is still lacking, and he recommends that in operations of gravity the surgeon and assistants should envelop their heads and beards in gauze turbans and bandages.

"Almost unconsciously," he says, "the hand may be carried to the brow, whiskers, or hair, to remove perspiration, which would be unfortunate, and would necessitate the renewal of the scrubbing process ere proceeding farther. It not infrequently happens that the most careful operator and his first assistant rub their heads together over the field of operation until dandruff and hair fall into the wound. This could hardly be detected except by a person not absorbed in the active part of the operation."

We commend Dr. Prince's suggestion to the attention of our surgical readers; and would add that it is rumored that there are at the present day no successful surgeons who wear long beards. In time to come it may be the surgeon, not the priest, who goes shaven and shorn.

ETIOLOGY OF IRITIS.

WHENEVER the iris becomes the seat of inflammation, it is fair to assume, in the absence of trauma, that some pre-existing vice diathesis or poisoning of the general system lies at the bottom of the mischief.

Syphilis, of course, is the most frequent cause of iritis, both in the early and later stages, while rheumatism stands next; but so far as the appearances produced by the inflammation are concerned, there is nothing to distinguish the syphilitic from other forms, unless it be the production of gummous deposits.

These are sometimes confounded with tuberculosis of the iris, but the diagnosis of the latter should be made with certainty in most cases, though it cannot depend solely upon the appearances and location of the lesion. The general condition of the patient must be considered, but aside from concomitant signs of the one or the other disease, we have to guide us the fact that the syphilitic lesion is usually single, and situated near the free border of the iris, while tubercle has its site of predilection near the attached margin. The former is of a brownish hue, while the latter is yellowish, or at times rose-tinted, from a fine vascular net-work over the surface.

In an interesting lecture on the etiology of iritis, Professor De Lapersonne recently stated his belief that iritis should always be looked upon as the result of an infectious process. This infection is not readily identified for each particular case, but in the manifestly infectious states —syphilis, tuberculosis, and lepra—iritis is well known to be especially frequent. Blennorrhagic iritis can readily be included, since it is beyond question at the present day that blennorrhagia may give rise to a general infection with systematized manifestations. Wecker has described an iritis of metritic origin, having its source in foci of infection located in the genital organs, and Grand Clement has spoken of a special iritic uveitis which he attributes either to a special microbe or to faulty elimination of organic waste products due to insufficient renal filtration.

The lecturer has frequently noted the coexistence of digestive disorders and iritis. This is especially the case where the stomach is dilated, and here much can be done toward the cure of recurrent attacks of iritis by appropriate treatment of the digestive tract.

It is difficult to prove that there is here an infection of microbic origin, but it may be admitted that septic products (ptomaïnes or taxalbumins) are reabsorbed from the digestive tube and produce the special irritation which determines iritis. At any rate it is always well to

examine carefully for digestive derangements when in the presence of an iritis, especially one of the recurrent type, not associated with one of the above-noted infective causes.

The rheumatic form of iritis takes on a new interest since the views put forth concerning an infective origin for all forms seem to agree with observations made upon certain pseudo-rheumatic affections depending upon infection, and also appear to be upheld by recent bacteriological investigations into the nature of acute articular rheumatism.

Professor Lahli (*Correspondenzblat fur Schw. Aerzte*, No. 1, 1892) reviews the work in this field and points out that Guttmann alone has succeeded in discovering bacteria in the contents of rheumatic joints during life. In a sero-fibrinous effusion, complicated with suppurative pericarditis, this observer found the staphylococcus pyogenes aureus. From post-mortem examination of a case in which during life no micro-organisms were to be found in an affected joint, Lahli succeeded in identifying the staphylococcus citreus, and by inoculating tubes obtained pure cultures.

This leads him to consider the latter organism as the probable pathogenic microbe of acute articular rheumatism.

Now, if the latter be proven to be really a staphylococcus disease, tracing the infection from the joint to the iris becomes a simpler, though by no means a perfectly simple, matter.

It would, however, add one more point of evidence in favor of De Lapersonne's theory that all iritis is of infectious origin.

A BILL TO PREVENT WITCHCRAFT.

We have received a copy of a bill "to prohibit electromagnetizing, mesmerizing, or hypnotizing human beings, or affecting one person through another, by electricity, and to declare the same to be a crime against the law of nations, and to define its punishment."

The bill contains the following enacting clause:

"*Be it enacted by the Senate and House of Representatives of the United States in Congress assembled.*

"Section I. Any person who, upon the high seas or in any arm of the sea, or in any river, haven, creek, basin, or bay, within the admiralty and maritime jurisdiction of the United States, who shall apply a current of electricity upon one person for the purpose of affecting another, or which does affect another, shall be guilty of a crime"—for which the punishment prescribed is death.

The bill, which might be called "An Act to hang witches," is accompanied with an elaborate explanatory document that aims to demonstrate the present existence of witchcraft or hypnotizing "one person through another," and the dangers thereof.

"Demonology," we are told "(under the name of hypnotism); in all of its forms is being practised, including the ingenerating, incubating, and inhumating from distances (on a large scale, *going into the millions*), as well as other practices of the demons INCUBI."

"The 'Augsburg Confessionals,'" the author of the bill says, "are situated in every country in the world where magical arts prevail, they are aided by an army of magnetizers numbering nearly a million, besides their assistants, the mind-readers, and mediums, who, together with most of the magnetizers, present that condition of *dédoublement de la personalité*, which enables them to penetrate the minds of others."

Particular emphasis seems to be put upon an alleged occult paper on æsthesiometry, published in the Medical Record, and written by Grace Peckham, M.D. The author of this alarmist bill will probably not succeed in getting his law passed, but he is going to contribute much to the gayety of nations if he keeps on.

News of the Week.

The Philosophy of Hats.—*The Lancet* discusses the question whether civilized man ought to wear hats, and comes to the conclusion that he ought. A safe conclusion perhaps would be that he surely will, whether he ought to or not. If one may reason from the experience of women, we might infer that should man discard hats and let his hair grow he would not be so bald. For baldness comes from hat pressure and infected barbers' tools. But man is a vain animal and prefers to adorn his head though he lose his hair thereby. The personal vanity of the male is directed chiefly to that part of his anatomy which lies above the clavicles. Males were the first to adorn the head, and will probably be the last to give up the practice.

Eighteen Thousand Dollars for Being Put Out.—A Dr. Buck, of Baltimore, has received a verdict for $18,000 in a libel suit against certain Baltimore physicians. When Dr. Buck came to Baltimore three years ago, he was admitted to the Maryland Homœopathic Society, after a great deal of discussion. He was expelled July 20, 1891, on charges of malpractice. Dr. Buck charged the defendants, who made the charges, with malice, and instituted suit.

Treatment of Cholera at Havre.—Dr.. Gaillard, of the Cholera Hospital at Havre, has reported the results of a mode of treatment followed by him at the extemporized hospital situated in bastion 36. Whenever a patient was admitted in the algid stage his body was at once vigorously rubbed, repeated hypodermic injections of caffeine and ether were given, as also inhalations of oxygen. If no benefit accrued two litres (for an adult) of the following saline solution were injected into the internal saphenous vein: Sterilized distilled water, 1,000 grammes; chloride of sodium, 5 grammes; sulphate of sodium, 10 grammes. This generally suffices to revive the patient. Sometimes, however, the transfusion has had to be repeated (once five times), but an interval of at least eleven hours is allowed to elapse between the injections. When the patient is able to swallow he is given a litre of sweetened water containing fifteen grammes of lactic acid. This is followed by champagne, coffee, and nutrient enemata. Dr. Gaillard's results stand thus: Cures, 173; deaths, 164; under treatment, 23—total, 360. Of the cases cured, twenty-five owe their lives to transfusion of sterilized serum. One operation generally sufficed; in three cases only was the transfusion repeated once. Fifty-two very serious cases were saved by the lactic acid treatment only, without transfusion. At the height of the epidemic there were as many as sixty-two male nurses in the hospital; of these, only one contract-

ed the disease, and he was saved by transfusion. The youngest of the transfused patients was aged eight and the oldest—there were three of them—fifty-six years.

Italian Congress of Medicine.—The programme of the Fifth Italian Congress of Medicine, which, as already announced in the *British Medical Journal*, will be held in Rome, on October 26th, 27th, and 28th, includes discussions on the following subjects: "Focal Changes in the Cerebellum and Curative Measures," to be introduced by Professors L. Bianchi and F. Vizioli; "Aërotherapeutics," to be introduced by Professors C. Forlanini and B. Luzzatto; and "Rheumatic Infection," to be introduced by Professors A. Riva and T. Gualdi.

Hearing the Nerve-currents.—At the recent Physiological Congress held in Liège, Dr. Wedensky, of St. Petersburg, contributed a series of telephonic demonstrations of the currents of action of nerves, and of the electrotonic variations of the excitability of nerves; these were specially interesting from the fact that the observer was actually able to hear by means of the telephone the passage of the currents along the nerves.

Antiseptic Oxygenation in Typhoid Fever.—Dr. B. W. Richardson, in *The Asclepiad*, recommends bichloride of methyline for internal use as being antiseptic, slightly stimulant, antispasmodic, and anodyne. The dose is from five to thirty minims. In particular he recommends it in typhoid fever, combined with peroxide of hydrogen, as follows:

℞. Methyleni bichloridi..... ʒ j.
Sol. hydrogen. peroxid. (10 vols.)..... ʒ j.
Acid. hydrochloric. dil... ..... ♏xxx.
Aq. destil.....ad ʒ vj.
M. Sig.: One-half ounce q. 3 h., in half a tumbler of water.

This he calls antiseptic oxygenation.

A Hard State to Practise in.—The Alabama State Medical Examining Board rejects 41.16 per cent. of candidates who apply for license. Either the standard is high or the applicants are low.

The Editor of the American Lancet says "Away with the Code;" but he says it in quotation marks and believes most sincerely that it should not be done away with. The matter is under discussion in the American Medical Association and a committee will report upon it next year. It is very unlikely indeed that the Code will be abolished; but some modification of it may be made. It is felt that the regular profession makes what may be called a political mistake in antagonizing dogmatic medicine and identifying it with quackery; the profession should antagonize dishonesty, and no Code can be too strong in formulating high standards of professional conduct as regards this point.

The Yale Medical School is to have a new building to accommodate the chemical and physiological departments.

Agathin is the name of a new anti-rheumatic and anti neuralgic drug recommended by Rosenbaum, of Frankfort. It is a salicylmethylphenylhydrazon; dose about ten grains (0.5).

One of the Medical Journals of Philadelphia is pounding away, in labored editorials, at the question of a revision of our Code of Ethics. This journal, under its present management, concedes that the Code needs revision. A few years since, such a statement from a New York doctor nearly caused a convulsion among editors in Philadelphia.

Dear neighbor, codes need not trouble you. What Pennsylvania needs is a good law creating a board of medical examiners. Improve the quality of physicians. Make them all pass an honest State examination, homœopaths and regulars alike, and codes will be unnecessary. A little more knowledge, and a little less, not of ethics, but of talk about ethics, is what the profession of this country needs.—*The Post-Graduate.*

A World's Congress of Climatology, Columbian Exhibition.—The committee on Medico-climatology (Dr. T. C. Duncan, chairman) has issued the following circular, entitled a preliminary address: "The year 1893 will be made memorable by the exposition that the world will hold in Chicago. There will be gathered not only the exponents of industrial wealth of the world in all the forms of material progress, but the advance made in art, science, and civilization will also be set forth. A series of congresses representing all of the departments of thought and scientific investigation is a true, even an indispensable, part of a world's exposition. In accordance with this idea, the world's congress auxiliary has been organized in connection with the world's Columbian exposition, and has been recognized and approved by the Government of the United States. Among the assemblages to be convened, what more fitting than that the department of medicine, the great healing art, with its many divisions, should be conspicuously presented? What more opportune time could have been selected by the climatologists of the whole world to meet and compare their observations and views on the different climates of the earth, and their effects upon humanity, and the diseases to which flesh is heir? With that object in view, a local committee of arrangements has been appointed by the world's congress auxiliary, and an advisory council will be selected from those eminent in this department in different parts of the world, to arrange a world's congress of medical climatology, to be held at Chicago during the exposition season of 1893. The design is to hold this congress at a time convenient to those who will attend the congresses of the other divisions of the department of medicine, which are assigned to open May 29, 1893. This early date was chosen to accommodate those who will desire to attend the medical congress to be held in Rome in November of next year." A preliminary programme is then suggested, and responses from those interested in the congress requested.

Syphilis and Breach of Promise.—The Court of Appeals of Kentucky has recently decided that syphilis, pleaded in answer to an action to recover damages for breach of promise of marriage, is a complete defence, following the decision of the Supreme Court of the State of North Carolina, in which the same defence was interposed and sustained in a similar action.—*Weekly Medical Review.*

Baron Léon de Lenval, of Nice, offers a prize of 3,000 francs to the inventor of the best application of the principles of the microphone in the construction of a portable apparatus for the improvement of hearing in deaf patients. Instruments for competition should be sent to

Professor Adam Politzer or Professor Victor V. Lang, Vienna, before December 31, 1892. The prize will be awarded at the Fifth International Otological Congress, to be held at Florence, in September, 1893.

The Chicago Clinical Review is the name of a new monthly, edited Dr. George Henry Cleveland and Dr. Albert I. Bouffleur.

A New Convalescent Hospital.—St. Luke's Hospital has received a bequest of house and land valued at $100,000, to be used as a convalescent hospital.

The Warren Triennial Prize of $500 has been awarded by the staff of the Massachusetts General Hospital to John Strahan, Belfast, Ireland. Subject, "Rickets."

The Entering Class at the Harvard Medical School, which it was expected would be small this year on account of the introduction of the compulsory four years' course, is, on the contrary, very large.—*Boston Medical and Surgical Journal.*

Pleuro-pneumonia.—The Secretary of Agriculture has issued a proclamation declaring that the United States is free from the disease of cattle commonly called pleuro-pneumonia. It is hoped that cattle from this country will henceforth be allowed free admission into Great Britain.

Whittier's Will.—By the will of the late John G. Whittier the Haverhill City Hospital receives a bequest of $1,000. After numerous other public and private bequests the will leaves "the remaining one-half of the rest and residue" of the estate, in equal shares, to the Amesbury and Salisbury Home for Aged Women, the Anna Jacques Hospital in Newburyport, and the Normal and Agricultural Institute for Colored and Indian Pupils, at Hampton, Va.

University of Minnesota.—The new medical buildings of the University of Minnesota have just been opened with appropriate exercises. The Governor of Minnesota made the presentation of the buildings to the Board of Regents of the University. Dr. William Osler, of Baltimore, made an address on "Teachers and Students."

Alleged Fraudulent Dispensaries.—In accordance with a call signed by thirty physicians of the down-town east-side district of New York, a meeting of the profession of that part of the city was held recently at No. 200 East Broadway, to confer as to measures for eradicating so-called free dispensaries for the poor where, says the call, 'the poor and ignorant are deluded and swindled."

Cocaine Cantharidinate.—Hennig (*Berl. klin. Woch.*, August 29, 1892) describes this preparation. It is more correctly termed a mixture than a chemical combination, but this is immaterial from the therapeutic point of view. It is a white powder, readily soluble in hot water. The author introduced it on account of the painlessness with which it may be injected. Swelling and infiltration at the site of injection occur much less frequently, and are less marked than with the other cantharidinates. Once only out of 2,845 injections did an abscess form. There was never any irritation of the bowels, and very rarely of the kidneys. Like the other cantharidinates, it not only acts beneficially in chronic catarrhal processes of the nose and throat, but also in early tuberculosis of the upper air-passages. It gave good results in tuberculosis of the lungs, skin, bones, and glands. In some of the cases injections of ½ degr. sufficed. It is contra-indicated in advanced tuberculosis as well as in albuminuria. If no improvement follow ten injections the treatment should be given up, and a further attempt made in six weeks' time.

To be Called a Doctor and Become Respected.—There is a legend in an ancient Buddhist manuscript of the early days of the physician of the Gótama Buddha, whose name was Jíwaka. It having become necessary for the youthful Jíwaka to select a profession, "he considered the character of the eighteen sciences and the sixty four arts, and determined that he would study the art of medicine, that he might be called doctor, and be respected, and attain to eminence."

As an Example of the Faith of a Lay Antivivisectionist when put to the test, Professor Victor Horsley relates an anecdote of the Duke of Newcastle, a vice-president of an antivivisection society. During a recent second epidemic of rabies the Duke's brother was bitten by a dog. The dog was killed, and the Duke took its dead body to Professor Horsley, at the Brown Institution. He was informed that the question whether the dog had rabies or not could only be decided by making inoculation experiments; the Duke assented, and frequent inquiries were made by a member of the family to ascertain the result of these experiments, which fortunately remained negative. This was a typical example of the hypocritical character of the agitation.

A Memorial tablet has been placed on the house at Bergen, in Rügen, in which Professor Billroth, who, on October 1st celebrated the twenty-fifth anniversary of his appointment to the Chair of Surgery in the University of Vienna, was born, on April 26, 1829. The tablet was formally dedicated by Professor Schmidt, of Leipzig. A *Festschrift* is being prepared by Professor Billroth's pupils, in honor of the jubilee, and the students are to have a *Festcommers*, to be followed by the usual torch-light procession in the evening.

University of Vienna.—From the prospectus of the University of Vienna for the winter semester 1892–93, which has just been published, it appears that last summer the number of students was 4,919, of whom 2,380 belonged to the medical faculty. Of these, 606 were "extraordinary" students. Among the foreigners the Russians head the list with 81, the United States coming second with 47. The active teaching staff numbers 60 professors, and 71 lecturers and assistants, who, during the forthcoming winter semester will give 190 courses of lectures and practical instruction.

The Southern Surgical and Gynecological Association will hold its fifth annual meeting in the city of Louisville, Tuesday, Wednesday, and Thursday, November 15, 16, and 17, 1892, under the presidency of Dr. J. McF. Gaston, of Atlanta. Members of the medical profession are most cordially invited to attend.

Proposed Higher Medical Degree in France.—The French Minister of Public Instruction has, it is stated, submitted to the Council of the Faculties of the Universities of France a proposal for the establishment of a medical degree superior to the ordinary M.D., carrying with it the style and title of "Docteur ès Sciences Médi-

cales" (Doctor of Medical Science). The utility of the proposed new degree is not apparent, but the mere fact that such a proposal has been seriously made in a country like France, where the titles question has no real existence, will serve to show what may be expected on this side of the Channel when we are all full blown Doctors of Medicine.—*British Medical Journal.*

The Treatment of Cholera Patients in New York City.—The Committee of Conference of the New York Academy of Medicine with the Board of Health respectfully submit the following report. On September 20th, the Committee received the following communications :

"HEALTH DEPARTMENT, 301 MOTT STREET,
NEW YORK, September 16, 1892.

"DR. STEPHEN SMITH, *President pro tem*, Conference Committee of Academy of Medicine, 574 Madison Avenue, New York.

"SIR : At a meeting of the Board of Health of the Health Department, held on the 14th inst., on motion of President Wilson, it was,

"*Resolved*, That the President of this Board be and is hereby authorized to invite the Academy of Medicine to examine, through its Conference Committee and others, the preparations made by this Department for the care and treatment of cholera patients in this city, and to confer with the Board of Health in respect to measures necessary to prevent the spread of the disease.

"EMMONS CLARK,
"*Secretary.*"

"HEALTH DEPARTMENT OF THE CITY OF NEW YORK,
301 MOTT STREET, NEW YORK, September 19, 1892.

"DR. STEPHEN SMITH, *President pro tem.*, Conference Committee of Academy of Medicine, 574 Madison Avenue, New York City.

"SIR : Having been authorized by the Board of Health to invite the Academy of Medicine, through its Conference Committee, 'to examine the preparations made by this Department for the care and treatment of cholera patients, and to confer with the Board of Health in respect to measures necessary to prevent the spread of the disease,' I respectfully extend such invitation to the Conference Committee of the Academy of Medicine, and would be pleased to be informed at what time and place it would be convenient and agreeable for the Committee to meet this Board and others.

"Very respectfully,
"CHAS. GEO. WILSON,
"*President.*"

In compliance with this invitation your Committee met the members of the Board of Health, and others, on the 28th of September, at the Willard Parker Hospital. Commissioner Bryant explained at length the preparations which the Board had made with reference to the apprehended appearance of cholera in the city. These consist of : I. Organization of a corps of medical inspectors for the immediate care of each case of cholera, and of the well persons who may be exposed to the disease. II. Ambulance service for the immediate removal of the sick to the hospital. III. Disinfecting corps to clean the room and disinfect clothing.

In practice, on information being given of the location of a case of cholera, a detail of physicians at once visits the house and takes charge of the premises. If the sick person must be removed they attend to his being placed in the ambulance, and one accompanies him to the hospital. Others attend to the isolation of the family in the room and of the families in the house, and maintain a strict watch over all persons who may have come within the limits of infection, during the period of possible liability to the disease. The disinfecting corps burns all soiled and useless clothing, and disinfects by boiling water all articles to be preserved which can be thus treated. The floors and furniture, and all closets and exposed areas or passageways, are washed with sublimate solutions. During the possible period for the incubation of the disease the premises are rigorously quarantined, and constant medical inspection of all exposed families is made to discover any cases of diarrhœa. If the immediate family of the sick person is destitute, it is removed to the hospital, and the members are regarded as "suspects," who require constant watch and care. For hospital purposes the Board has secured and fitted up the floating hospital of the St. John's Guild, which lies at the foot of Sixteenth Street and East River. The Disinfecting Department is under the direction of Dr. Biggs, and when some improvements are completed, it will answer every purpose required. The President, Commissioner Wilson, submitted plans for a new reception hospital, which were laid over for future consideration. The Committee then personally examined the floating hospital and all of its arrangements for treating the sick, the isolation of cases, the handling and care of clothing and bedding, the methods of preparing and serving food, etc. The disinfecting plant was then visited, and the methods of treating infected materials were explained by Dr. Biggs. On October 4th the Committee again met the Commissioners in conference on the plans of the proposed new reception hospital. It was then learned that the Board of Health has deficient hospital accommodations on the grounds now occupied, and that it is possible to obtain additional area on the same block from the city. The committee submits the following conclusions as the result of this conference :

I. The Organization which the Board of Health has perfected to deal effectively with cholera meets our cordial approval. We do not believe that cholera can prevail widely in this city if the methods adopted are energetically applied to the early cases. The success which has already attended this plan of treating individual cases gives the most gratifying evidence of its utility. II. The hospital accommodations on the St. John's Guild vessel are admirably arranged for the comfort and successful treatment of patients and the protection of the public from infection. III. The disinfecting service, under the supervision and direction of Dr. Biggs, is ample for any emergency, and will apply disinfection by all the most reliable means known to science. IV. The Committee endorses the proposition of the Board of Health to enlarge their permanent hospital accommodations at Sixteenth Street and East River, and urgently recommends that the proper authorities of the city be immediately applied to for the purpose of having the required lands set apart for that purpose.

Respectfully submitted, STEPHEN SMITH, M.D., *Chairman ;* EDWARD G. JANEWAY, M.D. ; A. JACOBI, M.D. ; RICHARD H. DERBY, M.D., *Secretary.* October 6, 1892.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, October 7, 1892.

CHARLES L. DANA, M.D., PRESIDENT, IN THE CHAIR.

The Treatment of Acute Arthritis of the Hip in Infants—Two Cases, with Recovery.—DR. V. P. GIBNEY read the paper (see p. 505).

DR. JOSEPH D. BRYANT expressed strong interest in the paper and in the exhibition of the cases, especially the last one. He had, not long since, had under observation a case in which he made the diagnosis of periarticular inflammation at the hip-joint. The boy, aged fifteen, entered the hospital having marked abduction and eversion, although there was no dislocation. There was high temperature and swelling, but no evidence of pus or fluctuation. The case was treated by extension, the limb gradually drawn around into correct position and immobilized by plaster-of-Paris bandage. He saw the patient two months afterward, walking about the wards without any difficulty.

He remarked that Dr. Gibney's last case suggested a question which might be difficult to answer, namely, what was there to prevent the bone slipping upward into the hip-joint and causing shortening, which, it was to be noticed, had not taken place. Apparently there was no structure to interfere except the capsular ligament, the head having come away. In dislocations at the hip the femur could be pushed up a considerable distance, causing shortening.

Another interesting fact was that so prompt a recovery had been made after simple evacuation, for the operator could not have seen all the crevices where the disease might have extended. He inquired of Dr. Gibney whether he thought that with the use of the limb would come shortening.

DR. GIBNEY replied that he supposed after four of five years some shortening would take place; he did not know how it could be otherwise.

DR. ANDREW H. SMITH inquired whether any of the periosteum had been left and was supposed to be taking part in bone reproduction.

DR. GIBNEY replied, possibly so; that the function was so good that whatever bone was at the joint it served the purpose of a head.

DR. GEORGE F. SHRADY remarked that the cases were of great interest as proving the good results of prompt evacuation of the abscesses. It was certainly very gratifying to note that there was no shortening after the removal of the necrosed head of the femur. He agreed, however, with Dr. Bryant in believing that such a condition would only be a temporary one. The full length was apparently due to infiltration within the capsular ligament, which in time would become absorbed and the limb become somewhat shortened.

DR. GIBNEY said this shortening was to be expected in time, unless, as Dr. Smith had suggested, there should be reproduction of bone.

DR. SHRADY added that if the destructive process had extended to the line of the capsular ligament it could not be expected that reproduction of bone would take place.

DR. A. H. SMITH inquired of Dr. Gibney whether he selected his time for operating, or whether the children came early enough to give any choice in this respect.

DR. GIBNEY said he would have operated earlier had he seen the patients earlier. Where fluctuation had formed in disease of the ankle, knee, or hip, in children, the staphylococcus aureus or albus was already present and an operation was indicated.

Dr. Gibney remarked, regarding the complete evacuation of the abscess and thorough cleaning out, that one should remember that the etherization in children should be made as short as possible, in order to reduce shock. If one spent a long time searching upon the ilium and down in the femur for all possible points of disease he might feel assured the child would have a hard struggle to recover. It was the rule of some very good surgeons to cut out all diseased parts within easy reach and to let the remainder alone, expecting nature to take care of further disease foci.

It was also important to distinguish between a tubercular process and a pyæmic process. The former was more likely to be persistent, whereas in the latter an operation, including free drainage, was likely to stop the septic poisoning and cause immediate improvement.

The class of cases presented this evening should be of interest to the general practitioner, inasmuch as he was liable to mistake them for the tubercular form, expect them to run a slow course, while in reality they quickly produced marked deformity, great emaciation, and might soon lead to death. Yet he believed that many cases which came under the notice of the orthopedic surgeon years later, with more or less deformity, were, at the beginning, of the kind shown by him, and which had ended in apparent complete recovery without deformity on opening the abscess, the later deformity occurring perhaps in the manner related by some of the gentlemen in the discussion. One of the worst cases he had seen was in a girl, aged sixteen, in whom the end of the bone had taken to moving up and down like a congenital dislocation, and could not be held down by any means which he had yet tried. Some brilliant results might, perhaps, be obtained if the general practitioner would learn early to distinguish between this class of cases and that of tubercular disease of the joint. Left untreated, the abscess was likely to burst into the pelvis or extend down the limb and lead to rapid dissolution. It was exceptional for the pyæmic cases to take place after the second year.

Vesical Stone Formed Around a Piece of Catheter.—DR. JOSEPH D. BRYANT presented several pieces of stone, with a piece of rubber catheter within, removed from a young man, about sixteen years of age. The patient had been brought to him by the family physician, who stated that about three years before, while catheterizing the bladder for some reason which he did not name, a portion of the gum elastic catheter had broken off and remained. The case illustrated the importance of removing any foreign body from within the bladder as soon as one knew it had been left there.

DR. SHRADY referred in that connection to the following case: A man, sixty five years of age, entered the hospital with a broken catheter in the bladder. The family physician had passed a rubber catheter, broke it off in the urethra, and while he had gone home for an instrument with which to remove it, a second physician was called, who attempted catheterization and pushed the fragment on into the bladder. Dr. Shrady introduced a lithotrite, fished for the catheter, at the same time trying to avoid injury to the mucous membrane. Finally he grasped the catheter a distance from the end, and while attempting to withdraw it it doubled upon itself, and, with the beak of the lithotrite, became locked in the prostatic urethra. This was an unlooked for complication, for he could neither push the instrument back nor draw it forward. The lithotrite was then made to bite its way through the part within its jaws and was easily withdrawn. He finally succeeded, by means of the lithotrite, in removing the different fragments piecemeal.

Another curious accident had once happened to him, while doing perineal section for tight stricture. An assistant, by some misunderstanding, neglected to remove a probe which had been inserted into the perineal wound. Supposing it had been removed, Dr. Shrady, after dividing a penile stricture, introduced a sound through the urethra, when he heard something click within the bladder. At first he thought it was a stone, but on introducing his finger through the perineal wound he found it was the probe that had been pushed before the sound into the

bladder. By putting two fingers of the right hand into the rectum, and one finger of the left into the bladder, he succeeded in turning the probe, which was transversely placed, so that it corresponded with the long diameter of the viscus, and finally removed it by grasping its presenting end with a pair of forceps.

Dr. Shrady in this connection referred to a very ingenious expedient, which had been resorted to by Dr. A. T. Douglas, formerly of Rondout, N. Y., but now of New London, Conn. His patient, a young lad, had succeeded during masturbation in introducing a glass tube through the urethra into the bladder. Lateral lithotomy was performed, when the principal difficulty presented itself in seizing the smooth and slippery foreign body without at the same time crushing it. Finally, Dr. Douglas coated the inside of the jaws of the extraction forceps with softened molasses candy and withdrew the glass without trouble. The candy was selected as the best substance for the purpose, and in preference to wax, which was first selected, as no insoluble nidus would be left in the bladder.

Dr. Andrew H. Smith was reminded by these curious incidents of some which had come under his observation. One was that of a medical student who had introduced a catheter into his urethra. It had entered the bladder, and was causing him much pain, so that he was obliged to let it be known what had happened. A surgeon introduced a large sound, gave an opiate and a diuretic, and told him to hold his water as long as possible. In this particular case this method succeeded, for the catheter did come away with a heavy gush of urine.

In a case in which a child got a bean into the ear the attending physician feared pushing the bean forward should he attempt to use the forceps, and adopted the cute idea of introducing through a guide the end of a brush wet with shellac dissolved in alcohol against the bean, and when it had dried drew it out with the bean attached.

The speaker, when a student, had himself once had occasion to remove a foreign object at the bottom of a deep wound at the elbow, and fearing injury to important parts should he use the knife, he dilated the opening with a tent, and thus was enabled to extract the object without loss of a drop of blood.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 8, 1892.

H. P. Loomis, M.D., President, in the Chair.

The Microscopical Committee reported that the examination of the lungs presented at the last meeting by Dr. J. Lewis Smith showed them to be the seat of a typical catarrhal or lobular pneumonia. No micro-organisms were found.

Horseshoe Kidney.—Dr. J. S. Thacher presented a specimen of horseshoe kidney. He had met with this anomaly only once before, and that was in an infant whose kidneys were presented to the Society a few months ago. In that case there was only one pelvis and one ureter. The present specimen was taken from a middle-aged woman, who had had no symptoms which would lead to the suspicion of such an anomaly being present. Each ureter was partially occluded by calculi, which had probably caused the extreme pyonephrosis which was also present. The two kidneys were united at their lower portions by a considerable mass of renal tissue.

Dr. S. A. Armstrong said that this condition must be quite rare, as he had only met with it once in a considerable experience in the dead-house, and in this case there was normal renal tissue even at the point of fusion.

Dr. George P. Biggs reported a case in which the connecting portion of a horseshoe kidney had been torn almost completely through, as a result of an injury. The patient was an adult, who had sustained a fracture of the body of the third lumbar vertebra by a truck running over the lumbar region. The connecting portion of the kidney was directly in front of this vertebra, and, as a result of the laceration of its substance, a very free retroperitoneal hemorrhage had occurred.

Absence of One Kidney.—Dr. Thacher also reported two cases of absence of one kidney, and as a proof of this, exhibited the base of the bladder from each case, showing only one ureter. Each of these patients had lived past middle life without showing any symptoms referable to this condition. One died of chronic pulmonary tuberculosis, and the kidney was found to be about double the normal size, and apparently healthy. In the other case the single kidney was the seat of a very extensive chronic nephritis, yet notwithstanding the great damage done to this organ by the long-standing inflammation it was able to carry on the renal function for a long time. This patient also suffered from endarteritis, hypertrophy of the heart, suppurative pneumonitis, acute pericarditis, and cerebral softening.

Dr. Armstrong said that he had once seen, in an autopsy upon a man who died of uræmia, a very much degenerated kidney, which was found to have been doing all the work, as there was only a mere trace of the other kidney, which had apparently been diseased in fœtal life, and had therefore never developed.

Thrombosis of the Heart.—Dr. George P. Biggs presented specimens from a case of this kind. The patient was a male, fifty years of age, who was admitted to the New York Hospital on March 29, 1892. His previous history was rheumatic and slightly alcoholic. One year ago dyspnœa was first noticed on exertion, and last November the urine became scanty and high-colored, the dyspnœa increased, and œdema appeared. On admission the apex-beat of the heart was found to be in the fifth space, four and a half inches to the left of the median line; no murmurs were heard; the pulse was rapid but regular, and of fairly good quality; there was considerable fluid in the peritoneal cavity, and there was marked œdema of the lower extremities, and, to a less degree, of the abdomen. Examination of the urine showed it to have a specific gravity of 1.018, and an alkaline reaction, but no albumin or sugar was found at this time. During the ten weeks he was under treatment the urine remained scanty and high colored most of the time; the specific gravity varied from 1.012 to 1.032, and the quantity of albumin from ten to sixty per cent. Ten days before death he developed Cheyne-Stokes respiration with bloody sputum, and the diagnosis was made of cardiac thrombosis with pulmonary infarctions. The patient sank rapidly, and died on June 6th. The temperature remained normal throughout. At the autopsy there was found extensive general anasarca, and a considerable quantity of fluid in all the serous cavities. The heart was hypertrophied and dilated, and weighed, when emptied of blood, twenty ounces. On opening the left ventricle a firm, cylindrical thrombus, measuring 8½ ctm. in length by 2 ctm. in diameter, was found on the anterior wall. Its surface was perfectly smooth, and evidently no fragments had been broken off from it. The left ventricular wall, corresponding to this attachment, was very thin, measuring from ½ to 1 ctm. in thickness, whereas in other portions the thickness was 2 ctm. In the branch of the left coronary artery running down the interventricular septum was found an old calcified thrombus, which nearly occluded the vessel. This accounted for the atrophy of the wall, and its conversion into fibrous tissue. No other thrombi were found in the coronary arteries, but they were extensively diseased throughout, small calcareous plates being found in various places. At the extreme apex of the right ventricle there was also a smooth, firm, and unbroken thrombus, about three-fourths of a centimetre in diameter. There were no thrombi in the auricles; the valves were normal, and the muscle substance was rather pale and soft. The lower half of the lower lobe

f each lung was filled with infarctions, some red and thers whitish, due to a thrombosis of the pulmonary ar-ery. Over the area corresponding to the seat of these nfarctions was an acute pleuritis.

Dr. J. S. Thacher said that within the past few weeks e had met with an almost parallel case, occurring in a oy. There was a large thrombus in the left ventricle.

Ulcerative Endocarditis.—Dr. Biggs also presented pecimens from this case. The patient was a male, venty years of age, a laborer, who was admitted to the lew York Hospital on June 5th. Four days before admission he had a severe chill, which was quickly followed y pain in the thorax, dyspnœa, cough, mucous expectoration, headache, and fever. On admission his temperature was 104.5° F.; respirations, 40, and pulse, 108. Over the lower lobes of both lungs there were crepitation nd slight dulness; the heart-sounds were almost imperceptible, the abdomen, spleen, and liver were apparently ormal, and his general condition was fairly good, with ne exception of occasional slight delirium. The urine ad a specific gravity of 1.022, alkaline reaction, and the nicroscopical examination was negative. On June 6th ne temperature in the morning was 103° F., and at midight, 106.8° F., with a pulse of 140. During the latter art of the day petechial hemorrhages were noticed in ne hands and feet. On the following day there was a narked increase in the delirium, with rigidity of the ack of the neck; the temperature rose to 108° F., and ne patient died in the afternoon of that day. The temerature immediately after death was 110.6° F. There ad been no secondary chill. At the autopsy, which as made two hours after death, rigor mortis was slight. etechial hemorrhages and larger hemorrhages were found enerally distributed over the body, but more especially ver the hands and feet, and on the anterior surface of ne wrist were a few pustules. There was no abrasion nywhere on the surface of the body except over one nee-joint, where one of the pustules had ruptured. The eart was normal in size. Between two of the cusps of ne aortic valve, extending along the inferior surface, as a soft, friable thrombus, from which portions could e easily detached. On the right segment of the mitral alve there was also a soft thrombus, which had been early detached. There were numerous endocardial emorrhages. On the surface of the heart were numerus petechial hemorrhages just beneath the pericardium, nd three small pustules on the anterior surface of the eft ventricle. The lungs were the seat of extensive petechial hemorrhages beneath the pleura; the left lower obe was intensely congested, but there was no consolidaon; there was a recent pleuritis over the base of both ungs, and some blood-stained fluid in the pleural cavity. The spleen weighed one pound. Portions of this organ were very soft, and on section these softened areas discharged thin grumous pus. The kidneys were rather arge, their capsules non-adherent, and scattered over heir surface were numerous small abscesses. and a few white infarctions which had not yet broken down. There was a slight deposit of fibro pus over the surface of the left lobe of the liver, and this lobe showed a large number of small abscesses on its surface, about the size of a pin's head. There was a small infarction near the base of the bladder, and this viscus contained about one ounce of purulent urine. Numerous infarctions were scattered through the intestinal canal. An examination of the pus from several of these abscesses showed apparently pure cultures of the staphylococcus. There was a large increase of serous fluid in the meshes of the pia mater of the brain and cord, but no purulent exudation. There were occasional small thrombi in the vessels, and in the lumbar portion of the spinal cord there was one small hemorrhage into the substance of the cord. The mesenteric glands were slightly swollen, and there were also three large cheesy masses from 1 to 1½ ctm. in diameter, scrapings from which showed large numbers of tubercle bacilli. The lungs, together with all the retroperitoneal and bronchial glands, were searched for further evidence of this disease, but none was found. No diagnosis was made during life.

Dr. Armstrong suggested that the presence of purulent urine in the bladder at the autopsy offered a possible clue as to the way in which the staphylococci gained entrance to the system, as he had known of fatal septicæmia resulting from the introduction of a catheter.

Dr. Biggs said that a careful examination of the entire penis had shown this organ to be perfectly healthy, and the purulent urine was evidently of very recent formation. He considered that the condition of the kidneys and of the bladder was a part of the general condition.

The Society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

VIVISECTION AT THE CHURCH CONGRESS—THE OBSTETRICAL SOCIETY—DISCUSSION ON THE VALUE OF ABDOMINAL SECTION IN CERTAIN CASES OF PELVIC PERITONITIS—SIR RICHARD OWEN—THE EPIDEMIC OF SCARLET FEVER.

London, October 15, 1892.

A discussion on vivisection took place at the Church Congress just held at Folkestone, and I understand that matters were rather lively. Dr. Wilks, Mr. Victor Horsley, Dr. Armand Ruffer, and the Bishop of Edinburgh maintained that experiments on animals were justifiable. Sir Andrew Clark was unable to be present, but sent a telegram expressing his strong sympathy with experimental research. Sir James Paget and Sir George Humphry sent letters defending the medical side of the question. Bishop Barry and the Bishop of Manchester spoke in opposition to the practice. Dr. Wilks pointed out that much prejudice and misconception had been brought in. The very use of the term "vivisection" prejudiced the question, since it implied the dissection of a living animal, whereas most experiments caused no more pain than a prick, or amounted only to the administration of a drug or some patent article of food. There had been no legislation on the subject until recent times, and that was directed not against the cruel practices of trade or sport, but against individual acts of cruelty distasteful to the observer and not affecting his personal interests. What the majority approved was not opposed. Mr. Horsley made a vigorous onslaught on the antivivisectionists, and scathingly exposed the *suppressio veri* of which Miss Cobbe and other lay opponents of vivisection have been guilty. Mr. Lawson Tait, he said, was inconsistent, for he denounced experiments in speaking to the general public, but as a member of the Scientific Grants Committee of the British Medical Association he did not oppose the granting of six hundred pounds a year for the furthering of the progress of medicine and surgery by scientific experiment. Mr. Horsley urged that the agitation was now only nominally humanitarian; it was really a phase of the line of thought which was constantly seeking to oppose science in the name of religion.

The Obstetrical Society held their first meeting for this session last week. Dr. Cullingworth, obstetric physician to St. Thomas's Hospital, read a paper (based on a personal experience of fifty cases) in which he discussed the value of abdominal section in certain cases of pelvic peritonitis. He maintained that recurrent attacks of pelvic peritonitis in the female ought always to lead to a strong suspicion of the existence of chronic disease of the uterine appendages, and to careful bimanual examination. Purulent collections in the pelvis were very apt to set up recurrent peritonitis, and he believed they were more common than was generally supposed. Where distinct swellings were found in the posterior quarters of the pelvis, in connection with recurrent attacks of pelvic

peritonitis, surgical relief was usually indicated; generally speaking, the sooner such relief was afforded the better. In purulent inflammation of the mucous lining of the Fallopian there was no outlet for the pus; a very slight swelling of the mucous membrane sufficed to block the tube at its uterine end, and any pus present in the tube must then either remain pent up in the tube or be poured out through the fimbriated end into the peritoneum, in either case becoming a source of danger. Salpingitis being painless, the wall of a pyosalpinx might be on the point of perforation before an acute attack of peritonitis gave warning of the presence of serious disease. It was safer to attack cases of pelvic suppuration from above than from below. Suppurating tubo-ovarian cysts were usually the result of ulceration on the tubal side of the adhesion between the tube and ovary. The author thought the immediate results were more satisfactory after complete than after partial operations. One of the chief risks in separating and removing inflamed tubes was the liability to mistake thickened and adherent intestine for diseased tube; the way to avoid error was to trace the tube from its uterine end outward. The exceptional persistence of pain after operation for gross lesions of the uterine appendages was generally to be explained either by omental or intestinal adhesions, or by the co-existence with the actual disease of a neurotic condition, of which the pelvic pain was a mere local expression. He regarded tubal disease in the virgin as being generally tuberculous, and thought that hydrosalpinx was in most cases merely a form of retention-cyst, due to occlusion of the distal end of the tube from without. Simple collections of serum, both large and small, were apt to form beneath the peritoneum covering the tube and broad ligament in chronic cases of pelvic inflammation; the best way to treat these cysts, after exposing them and making certain of the diagnosis by abdominal section, was probably by simple puncture and evacuation. Dr. Cullingworth observed that hæmatosalpinx, though usually due to tubal gestation with apoplexy of the ovum, was sometimes an incident in the course of a chronic salpingitis, and in these exceptional cases the walls of the distended tube, instead of being attenuated by the distention, as Bland Sutton had shown them to be in tubal gestation, were thickened by inflammatory deposits.

An animated discussion followed the reading of Dr. Cullingworth's paper. Dr. John Williams remarked that though he differed widely from the author both in conclusions and in practice, he felt personally indebted to him for bringing his paper before the Society, and believed the discussion would help to place the practice of opening the abdomen for pelvic disease on a sounder and more reasonable basis. He thought the title of the paper was misleading, for on examining the cases he found that twenty-four out of the fifty were cases of ovarian or other cysts, as to the propriety of removing which there was no doubt. He did not think it was justifiable to operate for tuberculous disease of the tubes, and especially where tubercle was found in other organs. The mortality of the author's cases was high, but he did not think it was higher than the mortality throughout the country generally. Many of the cases presented great difficulties. There was a mortality which necessarily arose from the difficulties of the operation, and this mortality was eliminated when operations of this kind were undertaken for trivial deviations from health. When considering the mortality of the operation, the mortality from the disease should be borne in mind. He had seen only two cases of death from ruptured tubes or abscesses, and he calculated that with a mortality of eighteen per cent. the mortality of the operation was several hundred times greater than that of the disease. As to permanent results, it was impossible to trace all patients operated on in a place like London, and under a government such as ours; that could only be done where everyone was under police supervision, as in Germany.

In about half the cases traced by Dr. Cullingworth more or less pain was present after the operation. In far as he could gather from the most reliable statisti about thirty per cent. of patients from whom diseas appendages had been removed were cured by the ope tion, many more were benefited and cured by time a other treatment, while the rest continued to suffer.

Mr. Alban Doran said it was good surgery to insu the escape of the pus and other products of inflamm tion, and Dr. Cullingworth's practice was sound in so f as that object was gained. Referring to MM. Péan a Segond's practice of vaginal hysterectomy for the cure pelvic suppuration, Mr. Doran said British surgeo would hardly adopt that operation. The patients oft recovered because the wholesale cutting allowed the fr escape of pus. Amputation of the thigh for hip joint d ease might also cure the patient by allowing of the fr escape of pus. In both cases good surgery demanded t same object by other means which did not include pe ous mutilation.

Dr. Champneys said he agreed in objecting to the ti of the paper. Pelvic peritonitis was a complication of large number of known diseases; he thought a good nu ber of these could be, and had been, diagnosed befo operation. Pelvic peritonitis was rarely dangerous life, and he was not convinced that it required abdomir section except in rare and exceptional cases.

Dr. Playfair spoke of the value of Dr. Cullingworth paper, but said that he could not at all endorse many the author's conclusions. Everyone would probably agr with the general principle that, when marked structu disease of the uterine appendages existed connected wi suppuration, a free exit should be given to the pus, and th such exit was often best obtained by laparotomy. But seemed to him that the author's surgical zeal carried hi far beyond this, and that his axioms, if generally adopte would lead to much rash, hazardous, and often unnece sary interference. He objected altogether, for exampl to the proposition that surgical relief was usually inc cated in cases where distinct swellings were found in th posterior quarter of the pelvis in connection with recu rent attacks of pelvic inflammation. Who could not r call many such cases which eventually recovered? Wh disastrous results would follow if every youthful and a dent gynecologist said: "Here is a swelling in the po terior quarter of the pelvis. Dr. Cullingworth says must be at once dealt with; therefore I must open th abdomen." That might possibly be all very well with D Cullingworth's surgical aptitude and experience; b even in his hands nearly one out of every five of his p tients died. What would be the results in hands le skilled?

The debate was adjourned until the next meeting the Society.

Sir Richard Owen continues about the same.

The scarlet fever epidemic in London shows no sig of abating. Eighty fresh cases were admitted yesterd into the hospitals of the Metropolitan Asylums Boar and three thousand six hundred and fifty eight cases scarlet fever are now under treatment in these hospital The mortality, however, continues very low.

Treatment of Cystitis.—Dr. Otis, writing on this sul ject in the *Journal of Cutaneous and Genito-Urinar Diseases* for August, 1892, does not favor local treatmer in the early stages of the disease, although he says that i some cases injection of a solution of silver nitrate int the prostatic urethra has produced a cessation of pai and of frequent urination. When the affection become subacute he recommends the injection of mild solutio of silver nitrate into the bladder, so as to fill it. In son cases he has used injections of bichloride of mercury s lution with satisfactory results, and in the chronic cystit of old men, especially when a good deal of mucus wa present, injections of salicylic acid have been found t be very beneficial.

ME THOUGHTS ON CONTRACT MEDICAL SERVICES.

To the Editor of The Medical Record.

R: In the issue of the Medical Record of October 1, 892, page 412, I noticed that the American Medical ssociation has under consideration the discipline of about x thousand railroad surgeons who practise under con- act. The word "contract" as applied to the services the medical profession is odious and repugnant, and is not to be wondered at and does not elicit any sur- ise when the profession, as represented by the Ameri- n Medical Association, protests against this character service. It must be borne in mind, however, that the ntract service to railroad companies is far more munerative, comfortable and pleasant than the con- act medical service of the army, and to this branch of ntract service, which is the most humiliating to a pro- ssional man, I think the American Medical Association ught to direct its attention primarily. The army con- act surgeon is a reputable physician; he performs xactly the same duties as the commissioned medical fficer; he is generally assigned to the worst or most isagreeable posts; he is paid a little more than half the lary of the medical officer whose duty he performs; he as no status with the troops, and he is not allowed to ear a uniform, neither is he allowed any vacation, with ay, whether he is taken sick while in the service or isabled by wounds received while in discharge of his uties.

Efforts have been made at different times to obtain gislation by Congress to ameliorate the condition of our rofessional brethren, who are contract surgeons, and Pro- essor A. Reeves Jackson, of Chicago; Drs. R. J. Dunglis- on, of Philadelphia; W. Thornton Parker, of Massa- husetts; William Balser, of New York; N. A. Robbins, f Brooklyn; H. A. Robbins, of Washington; and many thers, have labored zealously to accomplish this end, but ave been thwarted in their praiseworthy efforts by the urgeon-General's office at Washington. Even a bill hich was introduced in Congress by the Hon. E. J. Dunphy, and had for its object the granting of honorary r brevet commissions to contract surgeons who per- ormed the duties of medical officers during the late Civil Var, and wore the uniform of a first lieutenant of the rmy, which would cost the Government nothing but the aper it was written on, and which affected the status of ,532 reputable physicians, who enlisted for a period of ot less than three months, in accordance with army egulations and the second article of war, and which was he only branch of the medical staff of the army that eceived commendation as being composed of some of he "most eminent physicians and surgeons of the ountry,"[1] was reported on adversely by Congress, prob- bly on account of a report containing misstatements aade to the Secretary of War by the Surgeon-General of he Army (now retired), and by him (the Secretary of War) eferred to the Military Committee of the Senate and Iouse of Representatives.

This large body of physicians, with those of the regular rmy, volunteers, and militia, represented the patriotism of the medical profession in the late Civil War, and it eems to me, as a grateful recognition of patriotic ervices, that this slight request, which was fair and just, ought to have met the approval and assistance of their professional brethren in the Surgeon-General's office nstead of its persistent opposition. The following is an bstract of a letter which was sent me, which, I think, vill justify the committee of the American Medical Association in investigating this peculiar character of ervice exacted of the medical profession, and which I elieve, should be condemned.

"——, July 28, 1892.

I declined to accept a new contract in the army in ——, which gave me only $75 a month, and the service to be at one of the worst posts in ——, and one where there was no outside practice. I had served faithfully for twenty-one years continuously in ——, and this is what was offered me. I served in the war a couple of years, and, in all, my service amounts to about twenty-five years, and I am —— years of age. Now, I think it is a burning shame the manner in which we have been treated. My army life has, I believe, unfitted me for practice in this city, or anywhere, in fact, where there is but little moving about, and I am very loath to attempt it. I have been thinking that perhaps you could put me on the way to secure a position on a steamship plying between New York and Europe," etc.

This is only one instance of the ultimate result of contract medical service with the army. There is still employed in this manner another physician, who completed twenty-seven years of contract service, and who was wounded and lost an arm while performing his duties as a medical officer in an engagement. I am pleased to hear that the American Medical Association intend to take action on the contract service of physicians, but I trust it will commence with its professional brethren who are so unfortunate as to be obliged to accept the position of "contract surgeons" in the army in time of peace, with its small pittance. I would be pleased to give the Committee of the American Medical Association any information I possess on this subject.

John T. Nagle, M.D.,

Formerly Acting Assistant Surgeon, United States Army, and Commissioned Assistant Surgeon, 192d New York State Vol. Infantry; in charge of Third Division Cavalry, Camp Stoneman, Army of Potomac; Chief Medical Officer of Second and Third Divisions, and Reserve Brigade Dismounted Cavalry, Army of Potomac, which left Camp Stoneman, July 5, 1864, to join the Army of West Virginia, etc.

New York, October 17, 1892.

New Instruments.

A PRACTICAL TRANSILLUMINATOR.

By CHEVALIER JACKSON, M.D.,

PITTSBURG, PA.

The applications of transillumination in the examination of the upper air passages, as practised by Voltolini, are summarized by MacBride[1] as follows:

"1. Allowing a strong light to fall on the exterior of the nose, and then introducing a speculum from which all light must as far as possible be excluded.

"2. Throwing a strong light into one nostril while looking into the other.

"3. Introducing a mirror, as in posterior rhinoscopy, and throwing upon it a strong light while the anterior nares are inspected.

"4. Introducing an electric light into the mouth and inspecting the nose.

"5. Introducing a specially constructed electric light into the naso-pharynx. On looking into the mouth the velum is seen to be illuminated, while the introduction of a nasal speculum will enable the observer to examine the anterior nares, especially in their posterior parts.

"6. Introducing an electric lamp into the mouth, and observing the transparency of the antrum of Highmore and cheek."

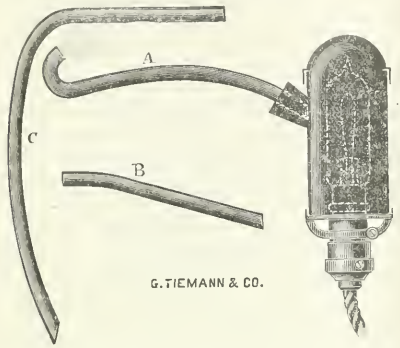
Voltolini's method of examination of the larynx by transillumination consists in the application of a strong light externally on the neck, in the region of the crico-thyroid membrane, while the larynx is examined with the laryngoscope in the usual way, but without other light than that transmitted through the tissues.

Vohsen has demonstrated the examination of the frontal sinus by transmission of light through the inner wall of the orbit.

[1] Diseases of the Throat, Nose, and Ear. London, 1892.

All these procedures, as practised, are not very practical, mainly because of the use of little lamps of low voltage (two to twelve). Such lamps get hot, often burn out, are expensive to replace, and at best furnish but little light; they require batteries or resistance coils, or both, and have many other drawbacks.

The writer has used transillumination for some years in his daily work, and finds it no less practical than ordinary rhinoscopy. In many cases it has added invaluable information otherwise unobtainable.



The apparatus used, which may be called a transilluminator, is shown in the cut. It consists of a German-silver lamp-box, polished within, blackened without, and containing a 50-candle-power incandescent lamp, of 50 volts for Westinghouse current, or 100 volts for Edison current. Projecting from the side of the box is a metal neck, into which fits a perforated asbestos cork. Through this cork passes a glass rod (A), which is silvered all over except the ends, the silvering being protected by a layer of enamel. The brilliant light within the box is transmitted axially through this rod, without lateral radiation, and issues from the distal end with undiminished intensity. A cloth skirt, not shown in the cut, hangs from the lower rim, preventing any radiation of light from the open air channel; and from the bottom of the lamp socket issues an ordinary flexible double cord, two metres in length, ending in an "attachment plug" An incandescent lamp anywhere can be withdrawn from its socket and this "plug" substituted, when the transilluminator is ready for use.

When the slightly warmed distal end of the glass rod is passed up behind the palate, and the patient's lips closed, inspection per anterior nares shows the nasal chambers to be brilliantly illuminated. A Lefferts hook should be used to draw forward the palate, while the tip of the rod goes into place, after which it is removed, and patient closes his lips around the shaft of the rod. A Chevalier Jackson tongue-depressor facilitates matters in retching patients; but it, too, must be removed after the rod is in place.

When the glass rod is placed on the tongue, distal concavity forward, brilliant and practical transillumination of the antrum is had. In this position, too, the nasal cavities are brilliantly transilluminated, the outer wall under the overhanging inferior turbinated more thoroughly than can be done in any other way. The single curved rod (B) is used where its shape is more convenient. The distal end in one nostril brilliantly illuminates the other nasal chamber; placed externally over the thyroid cartilage, the larynx may be seen with the laryngoscope to be a bright red glare. Thus can be executed the whole list of Voltolini's procedures, and many others. The room should be dark to get the best results.

The glass rods never become heated, wherein is a great advantage; they can be passed anywhere. The lamp-box, of course, does get hot, but this is not objectionable.

If desired, however, it can be made double-walled, w a layer of asbestos between, though this makes an exp sive instrument, whereas the other is cheap. If anyo has any use for a self-illuminating laryngoscope, a go one can be made by attaching the mirror shank to a c lar made to fit around the distal end of the single-curv glass rod.

Finally, it may be mentioned that the instrument w transilluminate a hydrocele, and with a short thick r will shoot a beam through an abdominal dropsy. T writer has passed a rod, shaped as shown at C, into t stomach, the light glowing brightly through the anter abdominal wall. While this has been put to no pr tical use, it may prove of service.

A DILATING TROCAR.

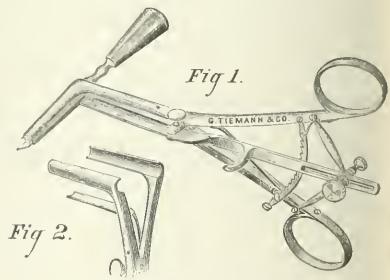
By DAVID C. LEWINTHAL, M.D.,

NEW YORK.

HAVING frequently had the occasion to treat cases pleuro-empyema under conditions in which operative terference, such as resection of rib or incision, wou through one reason or another, be impossible, I have be led to devise this little instrument, which I now present the profession.

It consists, as the appended cut clearly shows, of three-bladed dilating cannula and a trocar. The mid blade can be moved independently of its fellows, th enabling one to prolong the opening in any desired rection. A ratchet attached to the handles keeps t blades of the dilating cannula open when in use, while rather stiff spring shuts the instrument and keeps t trocar in place.

The method of using this dilating trocar is simp. An anæsthetic is, in my opinion, unnecessary in m instances. After a preliminary disinfection of hands, strument, and field of operation, the dilating cannula w trocar in position is thrust through the chest-wall, ho ing it so that the two lateral blades approximate t upper and lower ribs respectively, leaving the third in-



pendent blade free to work on the soft tissues betwe the ribs. The handles are now pressed together, thus se arating the three blades. The trocar is rapidly remov and the drainage-tube or tubes are introduced. The lator is now slipped out, and the operation is complet The whole procedure, done with care and deliberati need not last over half a minute.

I will here state, because it has been doubted by ph sicians, that the tissues of the intercostal space are ve yielding. It is quite easy to make an opening of a size by blunt dilatation without resorting to cutting struments at all. It may perhaps be advisable to ma a preliminary incision through the skin where an openi of large calibre is desired.

Considering the advantages accorded by this inst ment, it seems to me that it will entirely do away wi the method of incision so much in vogue in this count at the present time.

The dilating trocar has been used by me in several

stances, and also once by Dr. J. Horn, of this city. It has worked admirably in all cases. Although it has not as yet been put to such use, it has been suggested to me as being well adapted for opening cases of abscess of the lung, as the blades of the dilator would act as temporary tampons, until the drainage-tube could be introduced.

To sum up, the advantages offered by this instrument are: 1. The doing away with the anæsthetic. 2. The doing away with assistants. 3. The short duration of the operation. 4. The slight amount of shock incident to it. 5. Its safety as regards wounding the intercostal vessels. 6. The ease with which it is manipulated, thus putting it within reach of those who would or could not use a knife. 7. Patient fearing an operation requiring an anæsthetic would readily yield to it. 8. Its possible use in cases of abscess of the lung.

The instrument was made for me by Tiemann & Co., of this city, to whom I am indebted for the fine workmanship and its perfect mechanism.

I recommend this dilating cannula and trocar to my colleagues, and will be grateful to hear of the success it has met in their hands.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 22, 1892.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	51	15
Scarlet fever	62	6
Cerebro-spinal meningitis	2	4
Measles	42	3
Diphtheria	46	17
Small-pox	3	0
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Extra-uterine Pregnancy.—Dr. J. Whitridge Williams, of the Johns Hopkins Hospital, Baltimore, writes that he is engaged in the study of extra-uterine pregnancy from an anatomical standpoint, and he appeals to those who come in contact with this class of cases to aid him by sending him any specimens which they may meet. The specimens should be handled as little as possible, and as soon as possible after the operation placed in jars containing cotton, and covered by more than their bulk of ninety-five per cent. alcohol, or Müller's fluid, and sent to the writer. They should also be accompanied by a brief outline of the history of the case and the measurements of the fresh specimen. To any one aiding him in this way, he says that he will be glad to send a report on the specimen, and in his article will, of course, make due mention of those who have thus assisted him.

Education as a Therapeutic Measure.—In a paper read before the Social Science Association, on "Education in the Treatment of Nervous Girls," Dr. Louise Fiske Bryson says, in substance, that the therapeutic advantages of education are to be found in the study of subjects of permanent and universal interest, subjects that hold their own in youth and age, and when everything else fails or is outgrown. The particular interests of value, as discipline and delight, that time cannot wither nor custom stale, are general literature, history, social economics, and objective science. Shorter school hours, more time in the open air, more housework and accomplishments requiring bodily activity, better manners—which are minor morals—strict attention to neatness and conventionality in dress, the study of objects close at hand, familiarity with the recorded thought of mankind and knowledge of the principles that underlie the social condition, the government and practical politics, together with absolute regard to bodily health and sufficient rest, are some of the elements necessary to the real happiness and welfare of the nervously weak. Their shrunken individuality must be expanded by means directed at once toward repression of egotistic instincts, toward the enrichment and orderly arrangement of ideas, and through multiplication of acts and external relations, toward the energizing of the insufficient or diseased will. The education of nervous girls can be seasoned with something of art and a taste of foreign language. But the case is hopeless, in point of health when the æsthetic side is brought into undue prominence. Theoretic dressing, always dangerous, is especially disastrous for the class under consideration. To be like all the rest of the conventional world in mind, body, and estate, is their best ideal. The first duty of the guardians of nervous children is to instill the spirit of self-denial that has for its outcome graces of speech and movement, silence and self-command, pure tones and distinct utterances, together with tact and good spirits. The effort to be kind and sympathetic, in spite of physical weakness, lessens introspection and mental indolence and rouses activities otherwise dormant. Armed with grace and graciousness, uplifted by the society of good books, familiar with events and persons from whom civilization sprung, cognizant of the laws that govern the social condition, and with powers of observation and discrimination trained by study of science that "concerns all mankind for all time," it is possible for the nervous girl to become amusing and delightful as a companion, to grow in reliance and self-poise, and to attain value and usefulness as a citizen.

Sulphonal Poisoning.—Dr. J. B. Marvin describes a case where death followed two hundred and forty grains taken in five doses, two in the afternoon, and three the next morning. On the following evening the patient was sleeping heavily; pulse under 100; respiration, 32. When attempts were made to rouse him, he would yawn and turn over. The next morning his sleep was more profound, the respiration more rapid, the pulse faster and weaker; both pupils reacted to light, and there was no paralysis; the secretion of urine was abundant. The treatment was nitro-glycerine hypodermically.—*Boston Medical and Surgical Journal.*

Types and Treatment of Nervous Women.—Women have been much in evidence of late, especially the nervous variety. Of these there are three types to be met with in this part of the country, and are thus described by Dr. Charles L. Dana, in the *International Medical Magazine*, June, 1892. The first type consists of girls between the ages of fifteen and twenty-five, unmarried, anæmic, and showing a varied and peculiar train of symptoms. The second embraces nervous women between twenty-five and forty. And the third, those at the period of the climacteric. Nervous symptoms of the menopause are mainly vaso motor, and are in a measure due to physiological changes. About two-thirds of the nervous women who seek medical aid belong to the second type. Next in point of numbers come those at the climacteric. Nervous girls stand third numerically. There are comparatively few nervous women over sixty; and this quiet fact is, in many instances, at least, one definite and tangible compensation for the loss of youth. Young, nervous women are thin, anæmic, dyspeptic, of poor nutrition, and with special senses keen to the point of hyperæsthesia. The pupils are mobile, the heart irritable, the vasomotor centres unstable, and the extremities cold and clammy. These girls have spinal pains, and headaches of migrainous and other types, and suffer more or less at the menstrual epoch. They are quick, vivacious, observant, impatient, living on their "nerves," fond of excitement and indulging in amusements, for which they pay the penalty by prolonged exhaustion.

The second type is made up of what might be termed the wreckage of nervous girls and of healthy young women for whom life and domesticity have proved too great a burden. They are usually married, and sometimes prolific mothers, though the worst cases are among the childless. In this type, nervousness, weakness, insomnia, dyspepsia, morbid and depressing ideas, headaches and neuralgias, vertigo, tremor, and vaso-motor symptoms are dominant. Many factors produce nervousness in women. The causes are different and complicated in almost every case. In young women an original instability of the nervous centres is first to blame, then an irrational method of education, too little exercise and improper food, late hours, too little sleep and over-indulgence in amusements. The worst combination for bright young women is social dissipation and excess in the matter of study. It is impossible to indulge in a ceaseless round of gayety and be a good student too. Strain and worry then become a part of daily life, leading to disaster sooner or later. Among causes producing nervousness during the mid-age period—from fifteen to forty—are miscarriages, excessive child bearing, sterility, domestic troubles, fright, shock, malaria, infectious fevers, anæmia, and uterine disease. Treatment should be directed toward mitigating the constitutional neurotic taint, toward relieving the system of poor blood and irritants circulating in it, and toward removing exciting causes, whether reflex or those of environment. The wise selection of various general and symptomatic remedies is also an important part of the plan. The proper diet for most nervous persons is an essentially nitrogenous and fatty one, because it furnishes the most nourishment with the least expenditure of force. A regular life, work or exercise in the open air, plenty of sleep, are mentioned as the commonplaces of therapeutics. These ideals are not always attainable, even when intentions are of the best and docility unbounded.

The secretions of women are, as a rule, more acid than those of men, and this may possibly account for the more common nervous irritability of women. Three or four pints of water daily, to wash out the impurities, are to be prescribed, together with hot baths for a short time weekly, and cold baths daily, with vigorous rubbing, to aid elimination of dyspeptic, lithæmic, rheumatic, or other irritant. Alkaline waters may be given; or of a mixture of Rochelle salt, half an ounce; citrate of potassium, one ounce; bicarbonate of potassium, two ounces. A heaping teaspoonful may be dissolved in a tumbler of water, either hot or cold, and taken every morning. Mineral acids after meals, preferably muriatic acid, relieve the dyspepsia. Respiratory exercises are useful. Bottles, adjusted with rubber and glass tubes, and holding a gallon each, furnish a convenient apparatus for blowing a gallon of water from one bottle to the other. (Respiratory exercises according to Ling's principles are also of great service.) Drugs that are of value belong to the class of nervines, antispasmodics, and tonics. The bromides, when used, should be given in fifteen-grain doses, three times daily, for two weeks, then discontinued for a week before treatment is resumed. Valerianate of zinc, or bromide in the elixir of valerianate of ammonium, serves in hysterical attacks. Tincture of sumbul, of about the same value as valerian, is less disagreeable in odor. Nux vomica, which is better than strychnine, and arsenite of sodium, quinine, and iron, may be the only drugs required. Nux vomica should be given in increasing doses, up to thirty drops, three times a day, watching carefully to determine what dose will produce the best effect in each particular case. It should be given about three weeks continuously, and then there should be an interval of two weeks, this line of treatment ending in about three months. For nervous women who are greatly depressed, to the nux vomica three or four drops of the tincture of opium can be added. When there is much melancholy, quinine is of benefit; when, however, it cannot be borne in ordinary doses, Warburg's tincture is often tolerated. Salicin made from the willow is useful in neuralgic and arthritic cases.

Mechanical tonics, such as the water-cure, are often of greater value than medicines. There are three ways of using water as a mechanical tonic in the treatment of nervous women. First, in the form of a lukewarm bath, 95° F. for twenty or thirty minutes, generally at night, but it may be given at any moment of excitement or nervousness. The second is the wet pack, which "tends to increase the rapidity of tissue metamorphosis, indirectly to increase assimilation, and therefore promote absorption of nutritive material from the digestive canal," is tonic as well as sedative in its action. The third method is the shower, of which the best form is the Charcot or Scottish douche. The patient is placed about ten feet from the spigot, and cold and hot water are alternately directed upon the back. When this cannot be obtained, the ordinary shower-bath may be used, the patient standing in warm water in the bath-tub, and using first warm water and then cold water, from one to three minutes. If this cannot be borne, the next best thing is for the patient to stand in an ordinary bath tub in a little warm water, and sponge the body thoroughly with cold water. Electricity two or three times a week is useful, where there is spinal irritation or hysteria, in the form of a strong galvanic or faradic current. The most powerful tonic is a combination of the galvanic and faradic currents by means of the De Watteville switch. Static electricity has the most effect upon nutrition and metabolic changes. Athletics for young women is a field of promising chances. All girls should be examined, shown where deficiencies exist, and taught to make them up by gymnastic exercise. The author of the paper is evidently in sympathy with his subject, promptly acknowleding that "God made the women to match the men." Half the women in America are nervous. But they have no monopoly in this particular business, since to every three nervous women there is one nervous man. And one nervous man is quite a match for two nervous women.

Zola on Amputation at the Shoulder-joint.—M. Zola in his novel, "The Downfall," gives a dramatic description of a surgical operation: "The business that lay before him now was the resection of the shoulder-joint in accordance with Lisfranc's method, which surgeons never fail to speak of as a very pretty operation, something neat and expeditious, barely occupying forty seconds in performance. The patient was subjected to the influence of chloroform, while an assistant grasped the shoulder with both hands, the fingers under the armpit, the thumbs on top. Bouroche, seizing the long, keen knife, said 'Raise him!' seized the deltoid with his left hand and with a swift movement of the right cut through the flesh of the arm and severed the muscle; then, with a deft rearward cut, he disarticulated the joint at a single stroke and presto! the arm fell on the table, taken off in three motions. The assistant slipped his thumbs over the brachial artery in such a manner as to close it. 'Let him down!' Bouroche could not restrain a pleased look, as he proceeded to secure the artery, for he had done it in thirty five seconds. All that was left to do now was to bring a flap of skin down over the wound and stitch it in appearance something like a flat epaulette. It was no only 'pretty,' but exciting, on account of the danger, for a man will pump all the blood out of his body in two minutes through the brachial, to say nothing of the risk there is in bringing a patient to a sitting posture when under the influence of anæsthetics."

Drachm or Dram.—There has been some discussion among the doctors and druggists as to whether "drachm" or "dram" is the better spelling. Some of the large drug-stores settle the matter by spelling it "drachm" in the prescription department, and "dram" at the rear of the store, or at the soda-water counter.—*Florida Medical and Surgical Reporter.*

BLOOD IN THE URINE—HOW TO DISCOVER ITS SOURCE AND WHAT TO DO FOR IT.[1]

BY L. BOLTON BANGS, M.D.,

SURGEON TO ST. LUKE'S AND CHARITY HOSPITALS; CONSULTING SURGEON TO THE M. E. HOSPITAL, BROOKLYN; PROFESSOR OF GENITO-URINARY SURGERY AND VENEREAL DISEASES IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

AT the outset of this discussion I assume that the term "blood in the urine" refers to the presence in the urine of normal or intact blood-disks, and that no reference is to be made to that pathological condition known as hæmoglobinuria, or hæmatinuria. This condition, in which the corpuscles become dissolved in the blood, the hæmoglobin thus set free being excreted by the kidneys, is occasionally met with, but belongs to medical practice (strictly speaking) and is not pertinent to our subject. It must also be premised that blood in the urine is but one symptom, and may occur in many different pathological conditions. It is usually associated with other symptoms, but its mere presence is not diagnostic of any particular lesion, nor do its characteristics determine definitely from which part of the genito-urinary tract it exudes. It is true that it is often the first symptom for which treatment is sought, and although it may be the most dangerous, it is not necessarily the most diagnostic one. We must still remember that although the hæmaturia may be the most prominent symptom, it is but one of a group. The blood in the urine is but one of the factors in the diagnosis of its cause. In quantity it may vary from a few drops to a very great volume, enough to jeopardize the life of the subject, and it may be persistent, continuously present, or intermittent. When intermittent, the intervals may be from a few days to several years. In my opinion, neither its color nor its quantity will enable us to decide definitely whence it comes. Writers have declared that when the blood in the urine is bright red in color it indicated hemorrhage from the bladder; and when it was blackish or deeply intermingled with the urine, it indicated renal hemorrhage. But in my observation the color alone does not indicate its source, for in some lesions of the bladder we often have blood which is thoroughly intermingled with the urine, and the latter may be as black or deep in color as the urine which comes from the kidney. And on the other hand, I have seen bright red blood, sufficient in quantity to coagulate in the bladder, come from the kidney.

Blood may find its way into the urine from any of the anatomical divisions of the genito-urinary tract, or from one or more of these divisions at the same time. I believe, from my own observation, that blood in the urine from a source in the urethra may be overlooked. It is not sufficient to say that a "urethrorrhagia," whether from a traumatism or otherwise, is diagnostic in itself, for I have seen a sequel of gonorrhœa in the urethra permit blood to exude which escaped only with urination; nor is it enough to say that blood from the urethra will find its way out in the intervals of urination, and has no relation to the act. Blood can escape from this canal during the act of urination. The physiological action of the urethra may cause blood to escape from a diseased area sufficient in quantity to be commingled with the urine as the latter passes, and there be no appearance of it at any other time. The history of antecedent or present urethritis, and the absence of bladder or kidney symptoms, together with the fact that the blood is comparatively minute in quantity relative to the amount of urine, will lead us to suspect the urethra as the source of the hemorrhage, but the endoscopic tube will make the diagnosis definite. Just here permit me to suggest two cautions which may seem trite and puerile to you, but as I have seen it necessary to eliminate this troublesome symptom, I will remind you that sometimes the tube, when introduced into an inflamed urethra, especially if it be made to enter the membranous or prostatic portions, may press blood out from a hyperæmic locality. Also it must be remembered that in some individuals a granular or subacute urethritis in the bulbous portion of the urethra will so irritate as to cause the frequent and urgent calls to urinate which we are apt to associate with lesions of the posterior urethra or neck of the bladder. Without the use of the tube in such a case we might be led to consider the bladder as the source of the hemorrhage. I think I can appeal to your experience that this has at times puzzled you and obscured your diagnosis. Of course, the treatment of the diseased urethra will in such cases cure the hemorrhage. The diagnosis of hemorrhage from the urethra, in any of its parts, due to traumatism, surgical or otherwise, is determined by its cause and in its treatment is subject to ordinary surgical principles.

That the ureters may furnish blood for admixture with the urine as it traverses these canals there can be no doubt, as anyone who has ever witnessed the effect of an impacted calculus will admit; but as the pathological conditions of the ureters are so infrequent and so obscure, I will limit my part of the discussion to the differential diagnosis between bladder and renal hemorrhage.

The answer to the question as to whether the source of the hemorrhage is in the bladder or kidneys is often a very troublesome one. It introduces points of great complexity, and sometimes, indeed, the hemorrhage may be found to be from both the bladder and the kidney. We may say, in general, that hemorrhage from the bladder is much more abundant, more likely to clot, more persistent, and, when intermittent, with shorter intervals than that from the kidney. It is usually associated with some symptom of irritability or inflammation of the bladder, and also with some evidence of a lesion, ascertained by an exploring instrument or by bimanual palpation. The exploring instrument may detect enlargements of or projections from the prostate; it may detect, but not definitely determine, the presence of growths from the walls of the bladder, and it may detect the presence of stone or foreign bodies, but minute granulomata, soft papillomata, tubercular ulcers—all of which I have seen in my experience cause free hemorrhage—may entirely elude any instrument guided by the sense of touch. Fortunately, we are now able to bring to our aid another sense. With the cystoscope we are able to see the lesions, and make a differential diagnosis, and are able also to determine whether the blood comes from the bladder, kidney, or kidneys. But cases will occur in which we can get no help from the latter instrument, or in which it may be necessary to supplement the evidence furnished by it. We sometimes have cases of insidious disease of the bladder which give no objective symptoms other than

[1] Read before the Section on Genito-Urinary Surgery of the New York Academy of Medicine, October 13, 1892.

abundant and dangerous hemorrhage. I have had a case of (recurrent) papilloma of the bladder in which there was absolutely no symptom until the occurrence of repeated and prostrating hemorrhages. Furthermore, the hemorrhage was so abundant, and the blood was so rapidly and deeply intermingled with the urine, that the cystoscope gave no aid in the diagnosis. In this case the diagnosis was made, first, by determining the fact with the searcher that a foreign body was present upon the right side of the bladder; secondly, that the exploration of the bladder with the searcher increased the hemorrhage, and thirdly, when the bladder was emptied with the catheter and the last portion of its contents allowed to drain into a separate glass, this was noted to be redder in color and to contain more blood than the other portion of the fluid. The bladder was then washed repeatedly with an antiseptic solution, and at no time did the fluid return from the bladder without being tinged with blood. Each time, as the bladder emptied itself, it seemed to drain blood from the neoplasm directly into the catheter, and the last portion of the fluid was always darker than the first. In this case, the incision into the bladder and the removal of the tumor by the supra-pubic route of course instantly stopped the hemorrhage.

It has been my experience with the cystoscope, which, in spite of its occasional failures, should be regarded as an instrument of precision, to observe that hemorrhage from the kidney is rarely so rapid and abundant as to obscure the fluid medium in the bladder. Hence, if this does take place, in a given case, it may be regarded as one of the diagnostic points in favor of the lesion being in the bladder. But if the case which is presented for diagnosis has no symptom of disease of the bladder other than the hæmaturia, it will not do to assume that therefore the blood comes from the kidney. There can be no question that the latter—one or both of them—may supply an enormous quantity of blood, and sometimes without any particular effect upon the general well-being of the subject. Physiological and pathological facts both demonstrate this, but inasmuch as the question of treatment of the symptom involves the removal of the cause, we should carefully, studiously, and in order examine each of the organs from which the blood may come. Associated symptoms give valuable aid in determining the source of the hemorrhage to be in the kidney, and when obscure, or not present at the time of the examination, must be carefully sought for.

Lumbar pain, associated with blood in the urine, is a frequent accompaniment of lesions of the kidney. It may be only vaguely like the intensely severe colic which accompanies the passage of a renal calculus, but, especially if it be unilateral and minute clots be found in the urine, it is plainly valuable in locating the lesion. Manual exploration may also reveal in the kidney region the presence of a distinct enlargement or of an indefinite fulness, or of mere tenderness, but I will admit that these signs are not always present, and are not easily ascertained. Individuals vary so in the amount of adipose tissue about the kidney that no positive conclusion either way (for or against) can be drawn from the two latter symptoms alone, and it is only as one or both form part of a group that they are valuable. It should be stated here that a movable or floating kidney may be the cause of blood in the urine, and its investigation should not be omitted in a doubtful case. The microscopic examination of the urine which, "it goes without saying," is a matter of course in all genito-urinary cases, gives especially valuable aid in suspected kidney lesions by informing us of the presence of casts, crystalline and granular material, tissue of neoplasms, and epithelium. Important differential evidence is furnished by the "catheterism en deux temps," suggested, I believe, by Guyon, with which I suppose all surgeons are familiar, and to which reference has already been made. The fallacy in it, against which we must carefully guard, is that blood may trickle into the bladder from the ureters, coagulate, and be delivered at the end of the catheterization, stimulating the bleeding from a vesical neoplasm. I have been led to multiply the washings, and to add the device of pressure over each kidney and ureter in turn between the washings. Thus: The catheter is passed, and the last portion of urine gathered in a separate glass. The color and characteristics of this small quantity are noted, and the glass numbered and set aside for microscopic examination. The bladder is then thoroughly washed, emptied, and the last few drops of the fluid separated in another glass. The bladder is again washed, emptied, and the catheter allowed to remain a few moments, while deep, bimanual pressure is made over (for example) the right kidney and along the course of the right ureter. The fluid, which escapes slowly, and often only in drops, is also gathered in a separate glass, and set apart for microscopic examination. The bladder is again washed, and the manœuvre repeated with the left kidney and ureter. If the small amount of fluid which is gathered under these circumstances is tinged with blood, the strong probability is that it comes from the kidney, and subsequent microscopic examination of the fluid may convert this probability into certainty. This procedure may not be unfamiliar to you, but I was led to employ it by observing in two cases of pyelo-nephrosis that, after thoroughly washing the bladder, purulent fluid could be made to spurt from the catheter (*in situ*) by pressure over the diseased kidney. I may add that one of these individuals learned the art of emptying his kidney (so to speak) and gained so in well-being that he positively refused operation. The following somewhat complex case illustrates some of the points, and I beg leave to quote it briefly.

A gentleman, aged forty-six, intermittent attacks of hæmaturia in eight years, lasting a few days at a time. For the past three weeks profuse and persistent hæmorrhage. He noticed that the first gush of urine contained bright red blood, then the stream grew darker, and finally became a deep smoky color. No frequency of urination; no pain associated with the act of urination; no lumbar pain; no lumbar enlargements or tenderness. History of urethritis and subsequent attacks of frequent and painful urination. General condition was depreciating. Confinement to the house, and the taking of ergot, etc., made him complain of feeling wretched. Locomotion did not increase the amount of blood, nor cause pain. The introduction of a soft catheter was attended with some difficulty in the posterior urethra, and as it entered the neck of the bladder he complained greatly of pain, and immediately there was a gush of bright red, clotted blood, followed by very dark-colored smoky urine. I thought at first that I had to deal with a neoplasm at the neck of the bladder, especially as per rectum there was tenderness and a sense of fulness in this region. The washings, as detailed above, were then undertaken, and the drainings of each few moments were always tinged with blood. Microscopic examination of his urine showed free blood, a small amount of pus and epithelium; and of the drainings, free blood and a cast. Treatment of the posterior urethritis, to which the pus could be referred, relieved the pain and difficulty of introducing instruments, and exploration with the cystoscope (more than once) showed a normal bladder and bright red blood exuding from the left ureter. This was evidently in sufficient quantity to coagulate at the base of the bladder and be expelled with the first contraction of the viscus. The presence of a normal bladder, and the absence of signs of abscess, neoplasm (including tuberculosis), or calculus in the kidney or its pelvis, which at the end of eight years ought to be manifesting themselves, led me to consider the cause of this man's hemorrhage as congestion, due possibly to some form of toxæmia. The examination of blood taken from his finger revealed the presence of "plasmodium malariæ" in abundance. All instrumentation was stopped and his hemorrhage ceased abruptly under the administration of tincture of hamamelis, followed by quinine.

Of course, cases might be multiplied which would indicate the difficulties of diagnosis, but these are familiar to you, and it would only be a waste of time to attract your attention to them.

The second part of the question, namely, "What shall we do for blood in the urine?" is so directly connected with the treatment of its cause that we are immediately led to ascertain upon what pathological condition in the genito-urinary tract its presence depends. Here it must be said that in the time allotted it would be impossible to present these in detail, nor would it be practical, for I think our minds may be led to valuable results by considering the subject in a general way. The question involves often the treatment of the symptom as well as the removal of its cause.

The comparatively small amount of blood which escapes with the urine during an attack of gonorrhœal cystitis is, as a symptom, of little consequence, and it is only necessary to say to you that the treatment of the cystitis itself will cure the hæmaturia. But in the old man, with prostatic hypertrophy, who is bleeding profusely into his own bladder, the latter, perhaps, distended with clots and urine and making the most agonizing and violent contractions to expel its contents, the condition is entirely different. Here the shock of the loss of blood is added to by the violence of the suffering, and the question as to what shall be done is an exceedingly delicate one. Sometimes the very act of relieving a retention, and thus putting the bladder at rest, will stop the hemorrhage. Sometimes again, the quieting of the expulsive effort of the bladder by the use of opium (morphia), relieves the congestion (because, as you remember, on account of the anatomical arrangement of the vessels of the bladder, the more the bladder contracts, the more blood is retained in its veins) and stops the hemorrhage, and the clots that have accumulated in the bladder, becoming softened by the urine, are expelled in the form of magmata. My own impression is that in these cases catheterization should be avoided as far as possible, for it is in the knowledge of all surgeons that the introduction of infectious material into bloody foci very readily induces decomposition and sets up inflammation which may be far-reaching in its effects. Hence catheterization should be done under the most scrupulous antiseptic precautions and only when it becomes absolutely imperative to relieve the intense suffering of the patient. The question then arises, when the resort to the catheter is imperative, as to what to do with the clots. In some cases I have looked upon the presence of the clots as conservative; that is to say, the pressure of the clot, plus the contractile efforts of the bladder, has seemed to control the hemorrhage. But where the bladder is not comforted and quieted by the relief of the retention, and the clots are still present, it is evident that the bladder resents their presence, and of course the expulsive efforts of the bladder, by maintaining the congestion, add to the hemorrhage. The removal of the clots, then, in order to quiet the bladder, is in itself a hæmostatic procedure. I must withhold my approval of the injection of pepsine or peptonizing solutions of any kind into the bladder under such circumstances. Such materials easily decompose. They can scarcely be rendered so aseptic as to not run a very great risk of adding to the bloody contents of the bladder septic material. Hence I prefer to break up the clots either by the aid of some instrument, such as the lithotrite, or by careful and frequent ablution with an antiseptic solution to remove them gradually, or to reduce their volume to such an extent that the bladder itself can expel them. Should the hemorrhage continue and not be controlled by dilute astringent injections, one of the drainage operations, preferably by the perineum, may be undertaken.

The hyperæmia (congestion) of the bladder due to the presence of foreign bodies, including calculi, sometimes causes hæmaturia. It may be modified, and the hemorrhage stopped by rest in bed, careful ablution, and, if need be, the injection of dilute astringents (tannin, 2 to 100; zinc sulph., half grain to the ounce) not strong enough to irritate the bladder and cause its contraction, nor to form clots, until such time as in good judgment the foreign body can be removed.

In the case of neoplasms, whether benign or malignant, it seems to me that we can hardly wait—certainly not for any length of time—to counteract the symptom, for as a rule, when the cases present themselves to us, they are suffering largely from the effect of the loss of blood, that is to say, acute anæmia. In my opinion, good judgment requires that we shall proceed to open the bladder by way of the supra-pubic route and remove the neoplasm, if need be with a resection of a portion of the bladder, as speedily as possible.

As to the methods by which foreign bodies, such as calculi, should be removed, I have elsewhere given my opinion, and only refer to them now when they are causes of hæmaturia. When it has been definitely ascertained that the source of the hemorrhage is the kidney, another series of questions are presented to us for solution.

In hæmaturia due to traumatism of the kidney, such as result from falls or blows upon the renal regions, and where the associated symptoms are those of collapse and other evidence of excessive loss of blood in or about the kidney, I would advise unhesitatingly an incision, either lumbar or abdominal, which will give access to the great vessels of the kidney, and ligation of them. Records show the death-rate following traumatism and rupture of the kidney to be very high, and that it is usually due to the loss of blood, and not to the loss of function. It has been demonstrated that the kidney receives a supply of blood, moderate to be sure, from other vessels than the renal artery, sufficient at least to maintain the life of the kidney for a time long enough to enable the other kidney to accommodate itself to the increased demand upon it.

If the history points to the presence of a retained calculus in the kidney, that is to say, recurring lumbar pain, preceded, accompanied, or followed by the hæmaturia, and if the cystoscope locates the source of the hemorrhage, a judicious nephrotomy may be done and extraction of the calculus, if possible. It may be proper to say here that it has occurred to me, from failures of my own and from failures I have observed in the practice of colleagues to find stone in the kidney, that a wider incision through the kidney may be with safety and propriety made than I, at least, have been willing to make. Some investigations by F. Legueu[1] fortify me in this belief.

Hæmaturia due to neoplasms or tuberculosis of the kidney presents a question which I think must be determined by the individual cases. Roberts has shown, and with him accord the French observers, that with carcinoma of the kidney the duration of life is just about as long in the cases which have hæmaturia as in those which have not, and I am led to the conclusion that the hemorrhage alone is not a positive indication for a nephrectomy. The growth of the tumor, pain, the danger of infection to the rest of the body, and the possibility of the prolongation of life, provided always that the other kidney is normal, must lead the surgeon to decide whether nephrectomy should be performed or not. I think the same considerations apply to the individual in whom is developing a tubercular kidney. It is an interesting fact that the autopsy-rooms show that not only have purulent foci in the kidney, but tubercular ones also, been surrounded by a protective capsule, and the individual passed a moderately comfortable and lengthy existence, somewhat handicapped, to be sure, by a more or less degenerated kidney.

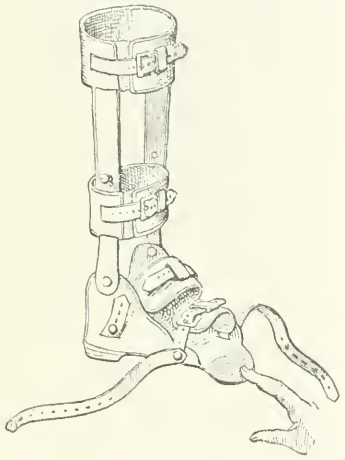
CONTRIBUTION TO THE TREATMENT OF CLUB-FOOT.[1]

By SIGFRED LEVY, M.D.,

COPENHAGEN, DENMARK.

THE manifold methods of treatment—apparatus, bandaging, manipulations, and operative procedures—recommended and used in the treatment of congenital pes varus might, to an outsider, appear as a proof that the treatment of this deformity is still, to a great extent, vague and lacking in the necessary scientific and empirical basis. Those who are constantly engaged in the treatment of deformities, and who are familiar with the nature of the lesion in question, know, however, that this variety of methods is less the expression of uncertainty than of the special difficulties which the treatment of pes varus



has to conquer, and of a number of individual peculiarities in every single case and in every single orthopedist.

It is not only certain that the congenital pes varus can be cured—this especially holding good without any restriction in cases where continuous treatment can be applied before the epiphyseal growth has stopped—but it is also beyond any doubt that this result can only be obtained when methods of treatment founded entirely on experience and deduction are serving us as a common guide, however different the methods or means are which each individual applies in their execution.

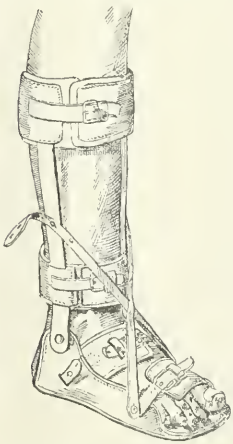
These remarks apply especially to the principle generally accepted nowadays, and adopted in cases which come under treatment directly after birth, the so-called American or Sayre's doctrine, according to which congenital pes varus should be treated as early as possible. Both experience and theory furnish weapons to defend the correctness of this doctrine against that of earlier surgeons, who held another opinion upon this subject.

This also applies to the principles followed in the treatment of pes varus at a more advanced age. In these cases the treatment may consist in forcible reduction by the hand or by one of the many apparatus in use, by "Etappeverbindung," by subcutaneous division, or by "open incision." The rule for the treatment is in all cases the same, viz., that which obtained a broad scientific base in Jul. Wolff's "law of transformation," which might be shortly expressed in the maxim: 1, Bring the osseous parts into their mutual normal position; 2, keep them in this position; and 3, make them act in this position.

Convinced, as I am, of the correctness of this fundamental principle as a guide for our treatment, and acknowledging the importance of the excellent scientific foundation which the "law of transformation" offers orthopedic science and treatment, I am equally sure that it is necessary to choose but those methods of treatment which allow us to follow the above-mentioned threefold injunction, and to reject, or modify, those which prevent its consequential accomplishment.

All methods of treatment must be tested and valued from this point of view. However, but one of these, viz., the immobilization by fixed bandage, which is so extensively used in the treatment of club-foot, will be tested here, mainly as giving an illustration.

A pes varus having been corrected, *i.e.*, the first demand of the above injunction having been complied with, a fixed bandage made of plaster of Paris, or other plastic material, may be of assistance to carry out the second, *i.e.*, keeping the foot in the corrected position. As far as the third demand is concerned, *i.e.*, the performance of the normal function, the fixed bandage, however, fails entirely. It actually impedes the function; it not only keeps the talo crural articulation, but also all the minor joints in front of this, fixed, and simultaneously the whole apparatus acting in the movements of these joints (muscles, ligaments, vessels, nerves etc., and even the nervous centre implied) are kept inactive, not for days and weeks only, but for months, and even for years. If, then, the "transformation" of the deformed osseous parts of the foot not only depends upon normal position, but also upon normal function, the protracted immobilization must be an obstacle to the "transformation" of the club-foot. Besides, or rather consequently, immobilization has an inseparable companion, viz., atrophy, the result being an augmentation of the atrophy which in all cases exists prior to treatment. Accordingly, after the discontinuation of the long-lasting immobilization a protracted and energetic battle has often ineffectually to be fought against this obstacle to normal function. Furthermore, the fixed bandage has an active influence in compressing the tissues it encircles. If we needed proof of the considerable, and often very destructive, consequences of long-lasting compression connected with immobilization, the sad experience obtained by the removal of the so-called "Dauerverband," in cases of minor surgical lesions, supplies ample material; but the examination of the stiff, pasty, thin, atrophic pes varus, which has been retained in a fixed bandage only for four to five weeks (not to mention three months), speaks distinctly enough in that respect.



These considerations lead us to the conclusion that protracted immobilization is a method to be rejected in the treatment of club-foot. I have for a long time, long before the "law of transformation" furnished me with theoretical arguments, abstained from using immobilization for a longer period than eight to ten days, for instance, never longer than until the tenotomy wound was tolerably healed, and I have taught others to act in the same manner. At the same time, I have endeavored to construct a retentive bandage, or splint, which was able to keep the corrected foot in position, without incurring the drawbacks of immobilization, and I think I have succeeded in this in the splint illustrated above.

It will be seen that the apparatus consists of two pieces, the junction of which is situated exactly in the plane of

[1] Read at the Sixth Annual Meeting of the American Orthopedic Association, held in New York, September, 1892.

the talo-crural articulation, and of which the one forms a double splint for the anticrus, while the other is a plate shaped splint with bent rims for the foot. The foot-splint must fit the foot exactly, and must not reach farther than the bases of the toes; it is furnished with two straps, which go through the splint on the edge between the plate and the bent rim. Of the two straps, the posterior acts on the talus region from the external side of the foot, while the anterior exerts a traction on the anterior part of the foot from the internal side of the foot. Besides, two elastic bands are attached at the extreme front of the foot-plate, intended to be fastened to the crural splint after crossing on the foot. In this whole splint we have an apparatus which can act with great force upon the reduced club-foot in all three deviating directions: the posterior traction, which acts upon the talus region counteracts the deviation toward supination; the anterior counteracts the adduction; and the elastic bands the plantar flexion. Besides, this splint does not hinder the natural function; walking (including the disengagement of the foot from the ground) can take place normally. Further, the splint can be removed at pleasure for dressing, manipulation, shampooing, etc.

Of course it is impossible for me to say whether this splint will prove as useful to you, gentlemen, as it has to me. However, I am certain that you will agree with me in saying that "immobilization is incompatible with transformation."

DRAINAGE AFTER PELVIC OPERATIONS AS INFLUENCED BY PRELIMINARY CURETTAGE OF THE UTERUS AND TRENDELENBURG'S POSTURE.

By WILLIAM R. PRYOR, M.D.,

NEW YORK.

It will not be controverted that drainage after intra-peritoneal pelvic operations is most undesirable, though often necessary. The principle of "when in doubt, drain," cannot be accepted as an axiom. It admits of a discretionary power which is unscientific; for doubt as to the propriety of the operative technique must obtain so long as the result of the operation is doubtful. Manifestly, then, any procedure which will render drainage unnecessary will be acceptable. But first, let us consider the disadvantages attendant upon drainage. By drainage I mean the employment of either a drainage-tube, or packing the locality to be drained with absorbent gauze, as suggested by Mikulicz. It may be accepted that all forms of drainage act locally, and not as drains to the general peritoneal sac, inasmuch as that sac is early shut off from the drain, and the field drained by a protecting wall of lymph. This lymph is due to a localized, non-septic peritonitis, unaccompanied by temperature or other constitutional symptoms. In fact, so benign is it in character, though often very extensive, that the function of the parts involved—the intestines—is seldom interfered with.

The disadvantages of drainage are, the discomfort to the patient accompanying the attention given the drain; the protracted convalescence; and the complications which so often follow the use of the drain. In view of the importance of drainage, discomfort to the patient, and even the protracted convalescence would not deter us in its use. But the complications due to drainage are so formidable as to warrant our most careful consideration of the subject.

The lymph thrown out around a drain is never entirely absorbed, but results in the formation of extensive and firm adhesions. A patient with such adhesions and bands is necessarily exposed to intestinal strangulation. Every drained cavity is subject to infection from without. In this way the ligatures employed become foci for suppuration and the formation of sinuses, or around them is cast a mass of lymph which remains permanent. But by far the most serious objection to drainage is the break it produces in the line of union, thus rendering the patient liable to ventral hernia—a condition to be radically cured by another cœliotomy only. And although this possibility is reduced to a minimum by employing my open method of treating the fat and skin layers of the incision, yet the accident does occur very frequently. It may be advanced that drainage is necessary in certain cases, and that the objections to it are insignificant in the light of the utility of the drain. This must, of course, be admitted when drainage is necessary; and it is most desirable to know when to look upon it as such. We must limit the cases which are doubtful.

For many reasons operators drain. Chief among these is the lack of faith in the operative method employed. The possible sources of infection are limited simply by the number of materials and persons employed in the operation. Therefore the simpler the technique the less the risk of infection. Drainage must do one of three things—remove a sepsis introduced by a foul operation, or a septic material present in the subject at the time of the operation, or a sepsis forming subsequent to the operation. For the first, of course, there can be no excuse, except when organs are removed already communicating with a cavity which it is impossible to render aseptic, as the intestinal canal. Any procedures which will limit the necessity for drainage must lessen the number of cases drained; and, as corollary, methods which necessitate drainage are to be avoided. Were it possible to remove diseased organs without evacuating their possibly septic contents, the indications for drainage would be confined to cases in which infection occurs subsequent to the operation, and to cases in which the general peritoneal or even pelvic cavity is already infected.

It might be well to consider the means by which infection may occur *post-operationem*. These are three—lesions to the intestines, which perforate even by minute openings after the operation; openings into a vagina not aseptic; and sepsis following along the lymph-currents from a focus of sepsis to open mouths at the field of operation. Injuries to the intestines are best avoided by operating when the patient is in such condition that there is least risk of such injuries, and by employing a method which enables us to avoid inflicting such lesions even where the risk is greatest. Operations done in attacks of acute peritonitis, associated as this condition is with distended and adherent guts—adherent not by mere bands, but, as it often seems, by very blending of broadly adjacent walls; and operations performed on growths which have old and firm attachments to the intestines, represent the two classes commonly met by the gynecic surgeon where intestinal wounds are at all possible. More or less extensive sloughing of the intestinal walls due to strangulation or ulcerative processes I will not consider. If we can avoid operating in acute peritonitis, manifestly it would be infinitely to the patient's benefit.

We are brought to consider pelvic peritonitis under many varied conditions. It may be offered as a postulate, that women have pelvic peritonitis so often and men so seldom because the former have uteri. So rare, indeed, is pelvic peritonitis in men that it is almost well-nigh a fact that the pelvic peritoneum can become infected through the uterus only. The male is exempt, and its existence in the woman is *prima facie* evidence that it has entered by means of the uterus. Pelvic peritonitis arising in this way has a fatality commensurate only with the size of the uterus and its lymphatics. It is more likely to prove fatal when the lymph streams are of advanced development and activity, and has less danger attached to its presence when these channels are diminutive and with limited function. Fatal pelvic peritonitis due to extension through the tubes must be of extreme rarity, inasmuch as the first and immediate result of such extension is the incurvation of the fimbriæ and their intimate adhesion, thus completely shutting off further tissue extension. The pelvic peritoneum is most fortunately arranged in that a not very extensive outpouring

of lymph will completely shut off from the general peritoneal sac septic processes in the pelvis. This limiting peritonitis is operative chiefly where the inflammation is due to extension from endometrium to endosalpinx to peritoneum, and only to a limited extent where the infection follows the lymphatics. To illustrate practically, rare indeed must be a fatal issue from gonorrhœal endometritis due to septic infection of a uterus not enlarged by pregnancy or neoplasm. Again, very frequently fatal is the peritonitis following removal of submural fibroids and abortion or labor. So then, if an abdominal section be done in this condition of acute peritonitis with a pelvic origin, the operation is performed under conditions which render possible injury to adherent intestines, and with the paths of extension of the causative sepsis still present and active. If this extension had come by the tubes alone, this one source of sepsis would be eliminated by the removal of the offending tubes and proper attention to the stumps. But the anatomy of the uterus demonstrates how unlikely this is when the infection is septic. Drainage to remove a continuing sepsis is indicated, unless, as I say, all sources of infection can be removed at the time of operation. Openings into a septic vagina may be made purposely when the vagina has not been properly disinfected, and accidentally. The indication seems to be that we properly disinfect the vagina previous to all laparotomies for pelvic lesions. Should such openings be made into a septic vagina or into the bowel, and at the same time such injury be done to the pelvic peritoneum as to render it agreeable to infection, closure of the rent and drainage are indicated.

In view of the rare fatality of acute pelvic peritonitis, unless occurring after labor or abortion or some condition in which the uterine development simulates either state, the question of the propriety of immediate operation arises. I do not believe such procedure can be other than rarely indicated, and therefore the question of drainage will but rarely occur in such cases, and our treatment must be directed solely to limiting the pelvic inflammation.

Peritonitis with a pelvic origin, when fatal, follows either rupture of pelvic abscess, labor, abortion, or unclean operations on the uterus. That peritonitis which follows labor or abortion is best treated by attacking the known source of infection, the inside of the uterus. Immediate operation (cœliotomy) for the relief of a pelvic peritonitis, which it is feared may become general and fatal, must be limited to cases of sudden rupture of pelvic abscess or infection of the clot of an extra-uterine gestation (hæmatocele). And if the infection here is of such extent that by operation all foci cannot be removed, drainage is indicated and unavoidable.

Pelvic peritonitis may remotely cause a number of lesions which will require operative procedures, and again it may be associated with gross changes in the adnexa which will necessitate their removal. In doing such pelvic operations there may be no sepsis introduced by the operator, and no escape of the septic contents of the diseased tissues removed. And at the same time large, raw, oozing surfaces may be developed by the separation of the diseased organs, notably in pyosalpinx and other inflammatory growths. It is just such cases which give rise to a doubt as to the propriety of drainage. The manner in which these adhesions take place as a result of peritonitis is worthy of note. To have such a condition occur requires two factors—the effusion of lymph and immobility of the organs. The surfaces covered by recent lymph first cohere, then the united lymph plates become highly organized and partially absorbed, producing a union which, on superficial inspection, appears as a continuity of tissue. But it is doubtful if the original peritoneal surface of the adherent organs is entirely destroyed, for by delicate manipulation they may be separated. Such separated tissues appear raw and oozing, but it is a prominent fact that they rarely present bleeding points of considerable size other than open venous channels. We may then look upon such bleeding as coming from surfaces not essentially raw, as we understand the term, but as proceeding from a new tissue which is organized, perhaps, but which is purely adventitious. If this be the true interpretation of these oozing surfaces, the blood produced by them should be considered, as it is blood escaping into the pleura or from a ruptured mesenteric vessel, or a broken vein in the pampiniform plexus; all of which provided such blood cannot become infected *post operationem*.

I have yet to know of anyone advocating opening a case of ruptured extra-uterine pregnancy, except to limit the amount of bleeding, to prevent threatened death from hemorrhage. Why is it that we look upon these raw surfaces as especially unfortunate occurrences and as requiring drainage? Surely the blood they produce is not different from that of the rest of the body—it cannot be particularly noxious. If by the operation no sepsis has been introduced from without, wherein lies the necessity for drainage? Experience has taught that it is better to drain such cases when the lesions are extensive; and frequently there is removed a large quantity of sero-sanguinolent fluid, an evidence in the operator's eyes of the propriety of his procedure. Although a perfectly aseptic operation may be done, these cases undrained will often die. The explanation of this, I think, may be found in the existence of enlarged lymphatics which extend from these raw surfaces to a septic focus in the uterus. These surfaces produce lymph; they produce blood. This lymph should be as innocuous as that thrown out around a drain. And it would be so were it not for the vessels producing it being in communication with a septic cavity. If this third source of sepsis can be removed there will remain no necessity for drainage. Acting accordingly, it has been my practice for some time, as a matter of routine, to always remove the endometrium as completely as I can some days before I perform a proposed cœlotomy, whenever I have the least idea that the endometrium is the seat of septic change. This I have done for additional reasons, but the one bearing on drainage alone interests us. Take for illustration a case of pyosalpinx, associated with acute peritonitis and a purulent uterine discharge. What conceivable objection can there be to thoroughly curetting the septic uterus, irrigating it, and packing with gauze? As a matter of fact, if done in an exacerbation of the pelvic inflammation it will generally cut it short. Does not this one fact show most clearly the etiological relationship between the septic endometrium and the acute process in the peritoneum? And by this preliminary curetting we remove the septic focus in the uterus upon which depends much of the necessity for drainage after the laparotomy, and to which I am convinced many failures in the operations are due.

And now as to the influence of Trendelenburg's posture in operations upon these pelvic inflammatory growths. It seems to me that the chief beauty of the posture lies in our ability to see what we are doing. But with it less ether is necessary, and bleeding from pelvic abrasions is reduced to a minimum. After the adherent intestines are liberated the general peritoneal sac is entirely shut off from the field of work by the diaphragm of flat sponge which is introduced. This also at once protects the bowel from our manipulations and from our antiseptic solutions; from all bruising and all irritants. In the removal of suppurative foci, should pus escape, it is readily seen and caught. Bleeding points are at once detected. Injuries to the intestines can scarcely occur if even ordinary care be exercised in separating them. If the uterine cavity has been rendered aseptic by the preliminary curetting and packing as I have suggested, if no sepsis be introduced from without by the operator, even large raw surfaces may be left undrained and without risk. In other words, so perfect can our method be made that infection must be autogeneal and occur after operation. It has been my practice to pack tightly against all raw surfaces a wad of iodoform gauze, twenty per cent., to be removed just before tying the last sutures. To operate after this pre-

liminary curetting, and in this manner, is to do a clean operation in a clean field. Above all things we do a dry aseptic operation. Drainage, then, must be limited to cases which are already septic, and to cases where we are not sure of our asepsis. The operator no longer need feel doubt as to the propriety of drainage unless he look with suspicion on his method. So far the arguments against this preliminary preparation of the septic uterus have been those based on fear and suppositious risks. And as to Trendelenburg's posture, not one objection has been offered which is tenable. But if the posture enables us to see as well as feel; if it renders flushing unnecessary; if by using it we are enabled to invade the pelvis only; if associated with the preliminary curetting of the uterus it renders possible an aseptic dry operation without subsequent drainage, can the advocacy of a horizontal posture, the short incision, the blind manipulation and bruising of the viscera, the irrigation of the peritoneal sac and the drainage-tube obtain? The one method exposes the acme of all our grand new surgery, the other the science of the rule of thumb. By the one is found a true aseptic clot for raw surfaces; by the other, the drainage tube and its complications.

15 Park Avenue

CLINICAL OBSERVATIONS ON TWO RECENT CASES OF CHOLERA ASIATICA.[1]

By J. HENRY FRUITNIGHT, M.D.,

NEW YORK.

It was my fortune to meet with the first and second cases of Asiatic cholera which appeared within the corporate limits of the city of New York during the recent visitation of that pestilence to our shores. Preliminary to a brief but concise clinical narration of these cases, I desire to say that never before had I seen a case of the disease, and what knowledge I possessed concerning it was obtained entirely from reading and from conversations with members of the profession who had had personal experience in previous epidemics.

For more than fifteen years have I been the medical attendant of this family among whose members the disease manifested itself. In this period of time they have had no more sickness than might befall any family. The family consisted of father, mother, and four adult children, three sons and one daughter. The father and sons always worked steadily, while the daughter assisted the mother in her household duties, as the latter did not enjoy rugged health. The father and mother emigrated to this country from North Germany more than twenty years ago. They have always borne a reputation for sobriety, industry, cleanliness, and thrift. The appearance of their apartments gave decided and unequivocal evidence of these traits of character. The house, No. 768 Eleventh Avenue, in which they have lived during the last eight years, is in a very good condition as regards cleanliness and sanitary arrangement. It is occupied by three families besides themselves, one family to a floor. The house, in fact, is far superior to most others of its class. The neighborhood in which it is located is not a particularly filthy one, and it is not at all overcrowded, for on the opposite side of the avenue are the large open grounds of the Stryker and Mott estates, unoccupied by buildings and extending from West Fifty-second to West Fifty-fourth Streets, and from the Eleventh Avenue to the banks of the Hudson River.

The family went out visiting very rarely, and had but little communication with the world about them. They had not come in contact, so far as they knew, with any person or object that had been exposed to the infection. They had not in years visited any person who had arrived from Europe, nor had they received visits from anyone who had recently come ashore. They even had not received any European mail for years. As a result of a rigid investigation in every direction, no history of exposure to the infection could be discovered. Yet I have a theory how the infection occurred, of which I will speak later in this paper.

William W——, tripe-butcher, aged fifty-two years, was first taken ill on Friday, September 2d. On the following day, W—— accompanied by his wife, went out of the city to pay a visit to relatives living at a little place called Athenia, near Paterson, N. J. At this time, Mr. W—— was suffering from a mild diarrhœa. While there he at first improved. But overindulgence in unripe fruit, with copious draughts of very cold well-water, caused a reappearance of his diarrhœa. Therefore on Tuesday, September 6th, the couple returned to their home in New York City. Early in the afternoon, Mr. W—— applied at a drug store in his neighborhood for an ordinary diarrhœa remedy, which was given him. This he immediately vomited. He had not vomited before this. At eight o'clock in the evening I was summoned, which was the first time that the patient was seen by a physician, although the symptoms had first appeared on the preceding Friday. The symptoms which the patient presented were similar to those which we find in aggravated cases of cholera morbus. As already intimated, no history of known exposure to the infection of Asiatic cholera could be discovered, and although the symptoms were violent they were not more so than I have frequently seen in cases of cholera morbus in years past. Furthermore, though the case was viewed with suspicion, the symptoms were not violent enough, nor was the appearance of the patient such as to suggest the existence of Asiatic cholera.

Sulphate of morphia combined with acetate of lead was given to check the diarrhœa, and subcarbonate of bismuth to control the vomiting. His diet was restricted and regulated in the usual manner. Cracked ice with whiskey was also ordered, and sinapisms to the abdomen. I saw the patient on the following day, and found him so well that I left word that I should not call again unless I was sent for. On this day, the eighth day of September, the patient was seen, however, by Dr. F. de Kraft, of this city, his lodge doctor, who had also visited him on the two preceding days. Dr. de Kraft also diagnosticated the case as one of grave cholera morbus. On the next day, the ninth inst., I was again called in the morning, as the patient had a return of all his symptoms. Still the symptoms were not at all typical of Asiatic cholera, and it was thought that the patient was suffering from a relapse. The same general treatment was followed as in the original attack, but unsuccessfully. I visited the patient at eight o'clock in the evening of this day, and found him in a very critical condition. Even at this time the appearances were not what one would expect to see in cases of Asiatic cholera. Pain he had very little, no cramps whatever in extremities, collapse not rapid nor striking, surface temperature not much depressed, conscious always. At six o'clock in the forenoon of Saturday, September 10th, the patient died. Upon the basis of the foregoing history a certificate was granted assigning "aggravated cholera morbus" as the cause of death. In the light of subsequent events this diagnosis was revised, and that of Asiatic cholera promulgated.

On Saturday evening, September 10th, in the morning of which day Mr. W—— had died, I was again hastily summoned to see Mrs. W——. I reached the house at eight o'clock. On entering the lower hall of the house I met Mrs. W——, who said to me: "Why, I am not sick; the boys are only frightened." Since six o'clock in the evening, just twelve hours after the death of her husband, the patient, who was sixty-three years old, had had a couple of large watery stools, but had not vomited, nor did she complain of pain. I prescribed five drops of Squibb's compound solution of opium, to be taken every three hours. At midnight I was again called, but Dr. Charles E. Young responded in my absence and directed a continuance of the treatment. At seven o'clock in the

[1] Read before the Northwestern Medical and Surgical Society of New York, October 19, 1892.

morning of Sunday, September 11th, I again visited the patient, when I found that she had had a number of large serous discharges during the night, but that now the diarrhœa had ceased. Incessant vomiting, however, had set in, she also complained of pain in bowels and cramps in legs, and the appearance of her features was a startlingly realistic revelation of what could only be exhibited in a collapse due to Asiatic cholera. The sudden onset of the symptoms, following so closely the death of her husband, their rapid termination in collapse, together with the fact that the plague threatened to invade the city, induced me to seek counsel. At half-past nine o'clock in the morning our colleagues, Dr. J. Lewis Smith, who passed through the last epidemic in this city, and Dr. Frank Grauer, and Dr. Charles E. Young, met with me at the bedside of Mrs. W——. At this time we found the patient in a very grave condition, although the vomiting was less frequent and the stools very small, as she was in a collapse. The skin was dusky in hue, the face was drawn, the eyes sunken, the nose pinched, and the lips compressed. The radial pulse was nearly imperceptible. The whole surface of the body was icy-cold and bathed in a clammy perspiration, while the thermometer registered 102° F. in the rectum. She was very restless and moaned incessantly, and since seven o'clock complained of abdominal pain and of cramps in the calves of her legs and in her arms. Her speech was incoherent, and decubitus was with thighs flexed on abdomen and legs flexed on thighs. It was the opinion of all the physicians present that the only factor lacking to justify the diagnosis of Asiatic cholera was the absence of the history of exposure to the infection, and that therefore, to determine positively the nature of the attacks, it would be necessary to make cultures demonstrating the presence of the spirillum of Asiatic cholera.

It is just here, in the first cases of the disease, that the diagnosis would naturally be surrounded with difficulties, and particularly so if no direct exposure could be traced, as in these cases. For on the one hand, if the diagnosis should have been announced without a positive foundation, the physician would be denounced as an alarmist and panic-monger. If, on the other hand, he failed to make the proper diagnosis, and it subsequently proved to be a genuine case of the disease, he would be accursed the land over for permitting the disease to gain a foothold. After it has been definitely determined that cases of the disease have appeared in the city, it will be comparatively easy to make a diagnosis from the symptoms alone. Therefore it was very necessary to be exceedingly cautious in announcing a diagnosis of Asiatic cholera, until every test known to us had been applied.

When a clear and exact history of exposure is lacking, although the symptoms may be just like those present in typical cases of Asiatic cholera, it will be impossible to make a differential diagnosis between Asiatic cholera and aggravated cholera morbus without a bacteriological examination. Nevertheless, from the clinical symptoms which Mrs. W—— exhibited, we favored the diagnosis of Asiatic cholera rather than that of cholera morbus. Our reasons were these: The rapidity of the development of the symptoms, the rapidity of the appearance of collapse, viz., within six hours after the appearance of the first symptoms, the external coldness and the internal rise of temperature, the parchment-like feel of the skin, which had lost all its elasticity and remained stretched when it was pinched up, the persistent vomiting, the large serous, odorless discharges from the bowels, though they did not present the characteristic rice water appearance, and the quickly fatal result, scarcely twenty four hours after the beginning of the illness.

It was decided to notify the Health Board of the case, which was done at 10.15 A.M. In the meantime, Dr. Grauer and myself awaited the arrival of the health official at the house of the patient. Within forty-five minutes after the despatch of the information the health inspector, Dr. Dillingham, reached the house, which is an evidence of the celerity which the Health Board displayed in the discharge of its duties in the presence of the dreaded plague. Dr. Dillingham carefully examined the patient, and coincided in the views expressed by the consultants earlier in the morning. Specimens of excreta were obtained from Mrs. W—— before death, and were taken away to the bacteriological laboratory of the Health Department for the cultivation of the bacilli. In due time the Board of Health issued its bulletin announcing that the comma bacillus of Koch had been found in the discharges, thus verifying our clinical diagnosis of Asiatic cholera. Demonstrations of these bacilli obtained in the W—— case have been made at recent meetings of several other medical societies of this city.

For obvious reasons, none of the discharges of Mr. W—— were obtainable at the time, and though some of the intestinal fluids were obtained from his cadaver, they were not available for bacteriological examination, inasmuch as the body had been embalmed.

When the symptoms of collapse had set in, champagne, sulphate of spartein, and camphor were administered to Mrs. W——, while the body was surrounded with flasks of hot water and liberally covered with sinapisms. Large enemata of normal salt solution were thrown into the rectum every half-hour, with a view toward establishing reaction. For a few minutes after each enema there would appear an exhilaration of the circulation, the pulse would come up, and a slight flushing of the face would be noticeable, and the expression of the eye would become more lively. The diet had been restricted, and consisted mainly of peptonized milk, bovinine, and egg albumin, with boiled water given in small and frequently repeated quantities. At five o'clock in the evening I again saw the patient, at which time she was in extremis, and she expired an hour later.

In this connection it is proper to state that, from the very first visit to Mrs. W——, stringent orders were given by me for the whole family to observe in regard to the subject of personal and local disinfection and prophylaxis. Solutions of carbolic acid and of corrosive sublimate were provided for washing of hands, utensils, and textile fabrics. Boiled water and thoroughly cooked foods were ordered. So thoroughly was this carried out that when Dr. Dillingham asked for any linen which might have been soiled by either patient, not a shred could be found thus soiled, and that no other member of the family, all of whom came in close contact with the patients, did not contract the disease, corroborates how thoroughly our prophylactic measures were applied.

The case of Mrs. W—— was a severely classical one of Asiatic cholera, typical in all its features, and in its entirety the converse of the case of the husband. Therefore, reasoning *a posteriori*, we concluded that Mr. W—— must also have suffered from an attack of Asiatic cholera, notwithstanding that his case lacked a typical appearance. Had the chronological order of these cases been reversed, the diagnosis of Asiatic cholera would undoubtedly have been made in the case of Mr. W—— without hesitation.

In reviewing the husband's case, I think that we may safely consider his earliest symptoms as due to an ordinary diarrhœal attack, and that the symptoms caused by the Asiatic cholera first appeared on September 9th, seven days after his visit to New Jersey. In the case of his wife the first symptoms occurred on September 10th, eight days after the visit to New Jersey. The incubation period is, I believe, from five to ten days. Both patients were in all probability exposed simultaneously to the source of infection, therefore. Near the little place in New Jersey which the W——s visited is situated Dundee, a town of many factories. This place receives its quota from every emigrant ship which arrives at these shores. Is it not possible that before the disease was detected, or even officially declared as existing, at Hamburg, and before quarantine was enforced in our harbor against arrivals from that port, the germs entered our gates and found their way to Dundee? And does it not in conse-

quence seem very plausible that the W——s, in some unaccountable manner, received the infection into their systems in their trip to Athenia? for the time which had elapsed between their visit to that place and the appearance of their choleraic symptoms just about equalled the time embraced in the period of incubation.

INTERRUPTED AND CONVERSION METHOD OF TREATING MALARIA;

OR, THE CONVERSION OF THE REMITTENT AND CONTINUED TYPES OF MALARIAL FEVERS INTO THE INTERMITTENT, BY INTERRUPTION.

By HENRY V. GRAY, M.D.,

ROANOKE, VA.

WHETHER a separate poison is imbibed by the system to create these distinct types of fever, is not before us just now for argument, but every physician or person at all familiar with malaria and its antics, is aware of the fact, that in some sections we have distinct agues, ending in fever and sweat, and in other sections there is an apparent immunity from agues, but an adaptability to the remittent and continued types. Any departure from a pure air is liable to create disease in those who are very susceptible, if that air is respired sufficiently long; but to create that which we pronounce the various algid types, there must be some peculiar or specific poison pervading the air. Certainly, we all fully recognize and appreciate this, when we examine the eruptive diseases. Indeed, every disease is a disease unto itself, with its peculiarities and operating causes, as much so as the various types of mankind; and it is only by a commingling of the poisons, and antagonisms, that an interruption can take place.

A typically pure air, Dr. Joseph F. Edwards tells us, is as follows: "Seventy-nine per cent. nitrogen gas, twenty-one per cent. oxygen gas, watery vapor, and ammonia." This, he says, "is ideal atmospheric air."

It strikes us, that if our chemical and scientific knowledge has placed us so far upon the road of hygeia, and her miracles, we are fast approaching a point where we can evolve a something which, while not yet tangible, may sooner or later be named and weighed by the scales of an exact science. If we know positively what a pure, living air is, we certainly will be, in the course of time, able to state its variableness, together with the special adulterants. Professor Flint, of New York, in his "Practice of Medicine," says: "The causation of intermittent fever involves a special morbific agent, commonly known as malaria." We will suppose, also, that this distinguished scientist refers remittent and continued fevers, when existing in malarial regions, likewise to special morbific agencies, either as a unit originating several types, or each type with its own special poison or micro organism.

While it is true that all persons living in a malarious climate are to a certain degree familiar with this "bad air," or miasm—which are synonymous with malaria—we know as little about the agencies at work in causing the fevers and cachectic states of this disease as the names representing it imply. We call it swamp fever, hæmorrhagia, and hæmaturia, and claim that some peculiar miasm comes up from the marshes, enters our system, undergoes a zymosis or fermentation, ending in chills (ague), fever, and sweat, and taking on both a continued and periodic form.

The ague or chill type, ending in fever and sweat, is the explosive form. The remittent and continued is the passive or non-explosive.

Who would not prefer to live in a section of country peculiar to the regular chill or explosive type to one in which the malaria enters the system to harass and annoy, making sallow and muddy your complexion, running you down, ending in regular continued fever or a melancholic, cachectic constitution?

My argument is, then, that we have two kinds of swamp fungus, or malarial poison. In the explosive or chill form we can feel assured we will have a good shake, fever, and sweat. Nature is at her best here in breaking up this poison. When a sufficient charge is introduced an explosion follows, and all the organs are violently excited and agitated. Reaction follows, and then come the fever and sweat. Great quantities of the poison are eliminated through it. A calomel purge and a few doses of quinine, given at the proper time, destroys this monster.

In the other type (the passive) there is a slow, insidious, deceptive "lying in wait." A large percentage of the members of a family feel badly under this influence, and are under the doctor's care most of the time. When they first come into the section they may be in blooming health. Wait, and they will find there is some unseen poison at work.

In the fall of 1886, the few physicians living at Roanoke, Va., had their hands full of malarial fever patients. Among the number I had two patients very ill with malarial fever. I treated them in the usual manner, one being very much benefited, but the other in the fifth week decidedly worse. I used from ten to twenty-five grains of quinine with each patient daily. My patients were Charles and William L——, the latter of whom was gradually getting worse.

Early one morning I was called up, and found him very ill—temperature, 107½° F.; pulse, 150. There was a whistling, rapid respiration; skin parched and arid; entire suppression of urine. I concluded to interrupt and advance this case. I threw the cover off, the window being open, until the patient was chilly. In the meantime I was getting hot water sufficient to fill a large new tub. I put the young man in this water, covering him up with blankets, only leaving his eyes and nose exposed. He remained in this tub of hot water fully half an hour, but his body and head were supported, and hot water was added from time to time. He broke into a tremendous perspiration. I ordered a drink of whiskey and digitalis, and, as he was about to faint, had him taken up and put to bed, wrapped in the blankets, with an extra dry one. He remained in these blankets until everything was sweat. Meanwhile I had his body rubbed at different points with hot, dry towels. I then commenced quinine again, giving him fifteen-grain doses every two hours for three doses. At 4 P.M. that day his fever left him, and I am glad to say he never had any recurrence.

Charles E——, cashier of the Roanoke Savings Bank, and brother of Mayor William O. E——, was taken sick this same fall, starting in with high fever, but no chill, which portended malarial fever. I pursued the same course with him, breaking up his fever. Both of these gentlemen have had good health ever since.

I will say in conclusion, that in the case of William L—— I did not use the quinine until the suppression of urine was overcome, having free diuresis and the skin in full perspiration. Had I used quinine before these emunctories were freely aroused, I would have killed my patient. I have made it a rule ever since, when cases are obstinate, to use the interrupted and conversion method.

Those living in that section where the second form of poison prevails should try the interrupted and advanced method. To interrupt and advance, you convert the second (passive or non-explosive) type into the first by reducing rapidly the temperature and chilling the body; then, by using the hot bath, you bring on a sweat. You must exercise judgment, of course, and be ready with stimulants and other supporting measures. Then is the time to make quick but useful use of quinine.

N. B.—You can chill and make your patient shiver by a few cold blasts from a hand bellows, or chill by placing your patient between ice sheets for a few moments, and then quickly putting him in a hot bath. Be careful in using coal-tar products, if at all.

The Next International Congress of Anthropology will be held in Constantinople, or, should events render that city undesirable as a place of meeting, in Athens.

TWO CASES OF NEURITIS.

By THEODORE DILLER, M.D.,

PITTSBURG, PA.

PHYSICIAN TO NEUROLOGICAL DEPARTMENT OF PITTSBURG FREE DISPENSARY; FORMERLY CLINICAL ASSISTANT TO THE CHAIR OF PSYCHIATRY AND NEUROLOGY, MARION-SIMS COLLEGE OF MEDICINE, ST. LOUIS; FELLOW OF PITTSBURG ACADEMY OF MEDICINE.

Two cases of neuritis exhibiting widely different characteristics, illustrating to some extent the remarkable range of manifestations seen in this disease, recently came under my observation. The first case is noteworthy on account of the very unusual causation. The second is a case of multiple neuritis of an extraordinarily severe type, which somewhat resembled acute ascending paralysis (Landry's paralysis) in its symptoms, and presented some difficulties in diagnosis. The second case further illustrates in part the course of multiple neuritis and other interesting features.

CASE I.[1] *Patient Struck by Lightning; Current Entered through Right Hand and Passed down same Side of the Body; A Distinct Mark Left on the Hand; Loss of Motion and Sensation in Right Hand which Grows Less as the Arm is Ascended.*—Miss T——, a young lady aged about twenty-five, a telegraph operator, while at work in her office during a thunder-storm, received a severe shock of electricity, the current entering her body through her right hand, which was at the key-board at the time the building in which she was working was struck by lightning. She was at once greatly prostrated by the shock, being, for a short time, rendered unconscious. Several other persons in the room, at the time the building was "struck," experienced slight shocks. All were seized with fear and consternation. A subsequent examination of the telegraph instrument showed that it was "burned out."

Miss T—— was at once taken to her home, where she was attended by her family physician, Dr. Nowry, who discovered a bluish-red streak of ecchymosis under the skin of the fingers and on the flexor surface of the arm. There was almost complete paralysis of the arm, the loss of motion being greatest in the hand, less in the fore-arm, and least in the upper-arm. The patient was considerably agitated mentally by the scare, and possibly by the current also.

When I saw her, a few days after the mishap, I found her condition as follows: There was general lassitude and weakness, as shown by her appearance. She had barely enough force in the fingers of the right hand to cause them to touch the palm. Motion at wrist very feeble. There was a little more power in muscles of fore-arm, and considerably more in those of the shoulder. There was anæsthesia and analgesia in the hand and arm, which, in a general way, without going into tiresome details, about corresponded to the motor impairment, *i.e.*, it was greatest in the hand and gradually grew less as the shoulder was approached. The patient complained of feeling "numb" and "queer" over the entire right side of the body. It seemed to her as though this modified sensation was exactly limited to the right side of the body, from head to foot, by a longitudinal line going through the middle of her body. There was some, but not a great deal of, loss of power in her right leg. The mark of ecchymosis on the arm noted by Dr. Nowry was, at this time, scarcely visible.

Remarks.—The electric current which prostrated the patient doubtless entered at her fingers, which were at the keyboard, and passing up the right arm and down the right side of body, made its exit at the foot. Skin, muscles, fasciæ, vessels, viscera, and nerves were penetrated by it. But the effects left behind were specially noticeable in the nervous system, particularly in the nerve-trunks. Moreover, the most profound effect upon the nerves was noticed at the point at which the current entered the body. This can be accounted for chiefly by two facts: 1. The great density of the current at the point of entrance. 2. The lessened power of resistance to disease of nerves remote from the cord. It is well known that the pain and destruction caused by a given electric current is directly proportionate to the size of the electrode. If, in the case of this patient, the same number of ampères of current had entered her hand through an electrode five times as large as the one with which it was brought in contact, the pain and molecular disturbance would have been only one-fifth as great. The study of peripheral neuritis seems to show that the power of resistance to disease of nerves lessens progressively as they proceed from the cord, the peripheral terminations being most liable to the influence of disease. Hence, the longer the nerve-trunk, the greater is the vulnerability of its peripheral endings.

I have called this case one of neuritis, although it is not an uncomplicated one, for other tissues besides the nerves of the arm and leg were involved. Besides, there were psychical symptoms and general prostration caused by the shock of the current and by fright. Under a tonic and sedative treatment, together with rest, the patient made a complete recovery. For obvious reasons, electricity has been omitted from the treatment.

CASE II.[1] *Paralysis Beginning in Right Wrist (First Symptom); Progresses Rapidly; Other Three Extremities Involved Simultaneously; Complete Loss of Power in all Four Limbs at End of Forty-eight Hours; Some Pain and Tenderness; No Loss of Control of Sphincter; Progressive Stage of Disease Lasts Six Weeks, after which Slow Recovery Begins; Tenderness along Nerve-trunks; Great Wasting of Muscles; Suspected Causes: Copper and Influence of Cold.*—F. A——, male; Swede; aged thirty-four; height, five feet eleven inches; weight, one hundred and eighty pounds. Has been in the United States two and a half years; wife and five healthy children living. Eight brothers and sisters living and healthy. Drinks very moderately; never gets drunk. Denies specific history. He has enjoyed excellent health up to time of present illness. For some months has worked as common laborer about the salt works at Natrona. But for five weeks immediately preceding the onset of the disease from which he is suffering, he has acted as furnaceman in the copper-smelting furnace of the works.

Without any premonitory symptoms, the patient (March, 1892), felt a weakness in right wrist which rapidly increased. Some few hours (ten or fifteen) later, motion in the other arm and in both legs became impaired simultaneously. This paresis in all four limbs increased with such great rapidity that at the end of forty-eight hours from the inception of the disease there was complete loss of motion in both arms and legs. Along with the paralysis, there was tenderness of the skin and muscles in the parts involved, which was specially noticeable when an attempt was made to move the patient in bed. This pain and tenderness was complained of a good deal up to the third week of the disease, since which time it has not been a prominent symptom. For the first ten days or two weeks of the disease, the patient exhibited a temperature of $99\frac{1}{2}^{\circ}$ to 100° F. At no time has there been incontinence of urine or fæces, or pain along, or radiating from, the spine. A few days after the onset of the disease, a flabbiness of the muscles of arms and legs became noticeable. Very soon after this, atrophy of the paralyzed muscles began and rapidly progressed for about five weeks.

I saw the man with Dr. Lincoln, four weeks after the onset of the disease. His condition at that time was briefly as follows: Almost complete paralysis in arms and legs. By a great effort, the patient can slightly flex fingers of left hand. Flabbiness of all the muscles of legs and arms. Marked atrophy of both deltoids. Considerable (but less) wasting of biceps, triceps, pectorals, and scapular muscles in both arms. Less marked, but

[1] I saw this case, and am permitted to report it through the courtesy of Dr. S. E. Nowry, of Wilmerding, Pa.

[1] This case was seen in consultation with Dr. Mark Lincoln, of Natrona, to whom I am indebted for notes on the case as well as permission to publish it.

perceptible, flabbiness and wasting of muscles of fore arms and of both legs and thighs. Upon handling there was considerable tenderness in the paralyzed parts. Moderate pressure along any of the large nerve-trunks in the arms or legs caused distinct pain. Deep pressure caused acute pain. No loss of sensation to touch, pain, heat, or cold. Muscular sense intact. No bed-sores or tendencies thereto. Pupils normal; react to light and accommodation. Patient cheerful. No mental symptoms.

Through a letter from Dr. Lincoln, dated June 27th (about two months after I saw the patient), I learn that the progressive stage of the disease lasted, in all, about six weeks; that the patient is able to slightly flex and extend hands and wrists; that functions of bowels and bladder continue unimpaired, and that patient is gaining a little in flesh. No special change so far as atrophy or tenderness is concerned. He seldom complains of pain. No response to galvanic, but a slight response to faradic current in the paralyzed parts. He can feel the current.[1]

By way of treatment, the patient is getting a pill containing iron, arsenic, and strychnine three times a day, and a daily application of the faradic battery. In the earlier stages of the disease potassium iodide and saline purges were administered, with a view of combatting any metallic and syphilitic poisons which might be in the system.

Remarks.—The question of the differential diagnosis between acute ascending paralysis (Landry's paralysis) and multiple neuritis naturally presented itself.

In view of the fact that acute ascending paralysis, although first described by Landry so long ago as 1859, is, as yet, not well known or studied (largely on account of the infrequency of its occurrence), it may not be amiss, in this connection, to give an outline of its symptoms. The disease is sudden in its onset. There first appears a weakness in the legs, which rapidly increases. Power of standing is lost in a few hours or days; with it there is muscular relaxation of paralyzed parts. Muscles of pelvis and abdomen next become involved in a similar manner; then the arms; finally, the muscles of diaphragm, and those involved in respiration, deglutition, and phonation. The paralysis ascends the bodily frame as a whole. There is tingling but no loss of sensation. Some flabbiness but no wasting of muscles. No change in muscles as regards electrical contractility. Sphincters intact. No bed-sores. No mental change. Slight elevation of temperature. Spleen enlarged. The disease may run its course in three or four weeks. It is apt to terminate fatally by involvement of the muscles of respiration.

The symptoms common to the two diseases are: very rapidly increasing paralysis; muscular relaxation without loss of control of sphincters or loss of sensation, and without high fever. In both, complete paralysis of the limbs is seen. Both run a rapid course.

But the case under consideration can be diagnosed as one of multiple neuritis, as distinguished from Landry's paralysis, from the fact that the paralysis did not involve the legs first, as is almost always the case in Landry's paralysis; that the paralysis did not progress beyond or involve any muscles besides those of the arms and legs; that there was marked change in the reaction of the paralyzed muscles to electricity; that there was marked muscular wasting (which is never seen in Landry's paralysis); and finally, that the patient has not succumbed to the attack.

In more severe cases of multiple neuritis, where the cord becomes involved, the differential diagnosis, according to Gowers, may be difficult or impossible. But from a consideration of the points mentioned, the diagnosis in this case ought to be tolerably clear. The differential diagnosis from spinal hemorrhage,[2] myelitis, and other spinal diseases will suggest itself, and needs scarcely be mentioned in this connection. I will only remark that entire absence of pains along, and radiating from, the spine, with the control of bladder and bowels unimpaired, would preclude a spinal origin in any case in which there was (as in this case) complete paralysis of both arms and legs.

Next to, or perhaps exceeding in interest, the problem which presents itself in connection with the diagnosis is the one relative to the etiology. In considering this question, one point stands out prominently, *i.e.*, the fact that for five weeks immediately preceding his illness, the man, who had all along been employed as a common laborer, worked in a copper-smelting furnace, employment to which he was unaccustomed. Is the illness occurring so soon after he engaged in his new employment only a coincidence? Or is copper poisoning at the bottom of the whole trouble? A careful search failed to discover a green line along the gums; nor did examination reveal any other direct evidence of copper-poisoning. Moreover, Gowers declares that metallic poisoning is an unlikely cause when the arms and legs are affected simultaneously.[1] Metallic poisonings affect the arms first. Gowers further declares that "an initial affection of the proximal parts of the limbs at the same time as the distal parts, suggests some other cause than alcohol, especially cold or toxæmia."[2]

From a careful examination of the man's habits, it does not seem that the causation can be attributed to alcohol. At his work, the man was subject to drafts and sudden changes of temperature. Dr. Lincoln suggests that the influence of cold under these conditions might be enough to account for the trouble; and he also suspects syphilis. In reference to the copper-smelting furnace, it may be said that other men have worked in it for years without suffering any illness. Yet I cannot help suspecting that the man has been poisoned by copper. Perhaps copper-poisoning and the influence of cold air together are responsible for the trouble.

Westinghouse Building, November 1st.

[1] Improvement has continued up to date—November 1st. Patient now walks and uses his arms fairly well.

[2] For account of symptoms of this disease, as illustrated by a typical case, see paper by the author in New York Medical Record, June 6, 1891.

Clinical Department.

CASE OF CHANCRE OF RIGHT UPPER LID.

By HENRY W. RING, A.M., M.D.,

new haven, conn.,

assistant surgeon manhattan eye and ear hospital, new york.

Miss Annie D——, aged seventeen, waitress, consulted me at my office, September 21, 1891. There was a small ulcer on the right upper lid, involving the tissues about the punctum of the upper canaliculus, and the skin and conjunctiva of the lid to the extent of about four millimetres. Patient stated that this sore was of three or four months' duration, at first seemed like a stye which would "gather and break occasionally," was painless, and annoying chiefly from the excessive secretions and epiphora. Of late the ulcerating surface was extending somewhat and the symptoms more troublesome. She looked well, and considered her general health good. Inquiry could elicit no specific history or source of contagion.

Touched ulcer with alum pencil, cleaned and sprayed with bichloride of mercury solution, prescribed boric acid wash and vaseline, and requested that she report in a week. She appeared in two weeks. The treatment had been valueless and the sore was about one-third larger. The edges were soft and easily broken down, and there was pultaceous secretion. The pre-auricular glands were now moderately swollen, and she admitted that she had had swollen cervical glands before.

Being convinced that this was a case of ulcerating chancre, now prescribed Squibb's twenty per cent. oleate of mercury, to be rubbed into the skin daily, and saturated solution of iodide of potassium, beginning with fifteen-drop doses three times daily, and increasing three

drops each day. Locally, to continue careful cleansing and vaseline.

Was next seen October 14th, one week later. The ulcerating surface was still more extensive, considerable redness and swelling of lid, the sub-maxillary, as well as pre-auricular glands were swollen, there were mucous patches on lower lip, one on right tonsil, and sore throat. Ordered chlorate of potash gargle, and slight increase in the amount of mercurial ointment used daily.

On October 21st the improved condition of the lid was very marked. The œdema and congestion had largely disappeared, and the ulcerating surface was half healed, as well as the patches on the mucous membrane of lips and tonsils. Throat no longer sore. She was now taking forty drops of the saturated solution of iodide of potassium.
